Preface

The importance of an appreciation of animal behaviour science and welfare is increasingly being recognized in a range of disciplines. Greater scientific attention to these subject areas over the last 50 years has increased both the quality of the research being undertaken and its application. While animal behaviour science has, for a long time, been seen as integral to the study of animal welfare, it is perhaps worth emphasizing that this text is not just for those with this interest. The principles of, and concepts explored within, animal behaviour are of relevance to those working in many other pure and applied fields such as the psychological sciences and conservation biology. Similarly, the importance of considering animal welfare by all those whose work might have an impact on other species is being more widely encouraged; it is no longer the domain of those concerned primarily with animals in captivity, such as in farms, laboratories, zoos or homes, but is also a concern for those who work to manage wild communities, be they feral, pest or under human protection for their conservation.

This concern is not simply a peripheral matter or distraction, but has a moral dimension too, and so it is important that we reflect and are guided by ethicists in our decisions when it comes to our interactions with other species. It is with this in mind that this text was developed. This publication has been an enormous undertaking, and would not have been possible without an excellent team of editors (Jeremy Marchant-Forde, Paul McGreevy, David Morton, Christine Nicol, Clive Phillips, Peter Sandøe and Ron Swaisgood) to whom I am particularly grateful, and the large number of academics who have so willingly given their time and shared their knowledge. I am struck by the generosity of so many in helping to ensure that this project became a reality and I believe this is largely because of a common passion for our disciplines and care for, and about, animals. I have learned much and it has been a genuine honour for me to work with so many distinguished scientists in compiling this text.

At this point I must acknowledge that any limitations to the text are probably mine (and at times difficult decisions have had to be made about the extent or format of some entries in the final run-through), and all credit must go to the many individuals who have contributed. Not only are the contributors outstanding scientists in their own right, but they have also worked hard to become clear and careful communicators of their subject. This is not always an easy task. The field is rapidly changing and, while new publications are constantly appearing, the objective of this text is to produce a reliable and thought-provoking point of reference for those working both directly and indirectly in the full spectrum of relevant fields. This includes higher-level students as well as established academics (especially those diversifying their

interests as outlined above) and those working practically in the field. This text is for you.

Science is concerned with reducing uncertainty and, in the applied zoological sciences, we must often make inferences, whether concerning the function of a given behaviour or its psychological basis, because we can never know the mind of another. This has been a particular challenge for those working in the field of animal welfare for some time, but it is also faced by those working in a range of rapidly developing pure and applied fields such as comparative psychology and clinical animal behaviour. None the less, with careful study and experimentation, we have gone a long way towards helping to reduce this uncertainty, as explained in many of the entries in this text.

Opinions inevitably differ on many matters of judgement and, while one function of this text is to try to increase the consistency of use of terminology that can give rise to confusion (the first entry in this encyclopedia on 'abnormal behaviour' is a good example of this), we do not seek to preach a particular opinion. Thus, in addition to trying to clarify key concepts, issues for consideration are also highlighted in many of the entries. I am sure some may hope for more information or perhaps a greater emphasis on some aspects, and to this end we have tried to suggest further reading where appropriate. As already mentioned, this work is a collection derived from the efforts of many and, I very much hope, that you as the reader will share in this process. If, as you read it, you have comments then you can help us by contacting either me or the publishers so that we can consider these points in any future revision. Drawing boundaries has sometimes been a difficult but necessary editorial decision and additional contributors are always appreciated; I am especially grateful to those authors who have stepped in quite late to fill gaps that became apparent as we edited the entries and recognized additional cross-references we wanted to cover. Some I know personally, others I do not, but I will happily buy you a drink should we meet!

In order to try to limit the length of the text, there is substantial cross-referencing throughout, and I suspect that if you started with almost any of the substantive entries and then committed to read all the associated cross-references, you might well end up reading the whole book before you are finished! Another feature, aimed at trying to limit the length of the volume, is to consider some topics within related entries. For this reason, it is important that the reader uses the index when seeking information, rather than depending on being able to turn to the relevant letter in the main part of the text. The index, too, is cross-referenced.

This and many of the other production tasks have been undertaken by a dedicated team at CABI to whom I am also

very grateful, especially Rachel Cutts, Quentin Scott, Tracy Head, Claire Parfitt and Rebecca Stubbs. I must thank my family, my wife Connie and my two young sons Stefan and Tomas. This project was conceived before Tomas was born, and I know they have themselves given up much to allow it to come to fruition. They have supported me throughout and put up with me locking myself away when I am sure they would have preferred we were together. I am forever grateful to you, and hope you appreciate that you too have played your part in producing something of a unique text, which is aimed at helping those who want to deepen their understanding of the science and philosophy of applied animal behaviour and welfare, for the betterment of others. One of the joys of educating others is that you never know what others may

achieve with the knowledge you share, and so I would also like to thank all my tutors and colleagues who have helped me to become the person I am, and especially Sir Robert Hinde, whose guest lecture in Bristol on the interdependence of the behaviour sciences and subsequent correspondence over 20 years ago, convinced me of the importance of a text such as this.

In this vein I would like to conclude by thanking you, the readership. This text is dedicated to you, in the hope that you may be inspired and share our enthusiasm for science with others.

Daniel Mills
September 2009

Foreword

Every waking moment billions of photons stream into our eyes, our ear drums resonate with arrays of complex fluctuations in air pressure and data-streams from throughout our bodies pour through sensory nerves into our brains. Luckily for us, we (our conscious selves) do not have to deal with this ceaseless gushing of raw information as it sprays in as if from the flailing end of some severed broadband fire-hose. Within milliseconds, the tireless crews of our subconscious processing departments have it all neatly reviewed, sifted, assimilated, tidied up and summarized. And, aware of our limited capacities, they politely present the key points to us, colour coded for simplicity wherever possible, so that we immediately understand, for example, that *'there's a wasp on my apple'*. (For a fuller, proper, and very neat, account of consciousness, see within).

Progress in any subject is dependent on a similar process: information gathering followed by identification and elucidation of key patterns, higher-level conclusions and principles. Interest in animal behaviour – and all the other disciplines that inform assessments of animal welfare and practical measures to be taken to ensure or improve it – has increased dramatically in recent decades. This has resulted in a correspondingly huge

proliferation of information, conclusions and opinions. Review, sifting, assimilation and summary are essential to facilitate understanding of developments across this large and varied field to make it widely accessible and to provide a basis for future progress.

It is clear from the pre-publication drafts that an excellent job has been done of distilling large amounts of complex information into easily assimilated packages and I look forward to reading the entries and essays that I have not yet seen. The contributions cover a wide field and are very informative, interesting and well and engagingly written. In producing this book, Daniel Mills, his editorial team and the contributors (numbering almost 200) have managed to overcome the daunting challenge posed by the scale and complexity of the task (there are some 1000 entries) and, in so doing, have provided a very valuable service for everyone interested in the field and for the future development of it.

Abandoned animal

An abandoned animal is any animal whose previous care by another has been relinquished. Animals abandoned by humans as opposed to their parents (see: **Mis-mothering**, for example) may be given over to the care of another, as occurs in the case of surrender to an **animal shelter** (see also: **Animal rescue**), or released into the wider general environment. In either case, the previous carer may be distressed by the decision to sever their relationship. Some relinquishers may consider the release (abandonment) of their animals into the general environment as a more humane option ('giving the animal a chance to live naturally'), even though legislation that prohibits this may exist, while others may consider this type of action irresponsible and seek another to take responsibility of the animal.

Studies throughout a range of countries suggest that behavioural problems are the most common reason cited for the surrender of animals to animal shelters in the industrialized world, even though it has been suggested that these may be under-reported by relinquishing owners in an attempt not to reduce the chances of the animal being rehomed. The most common reported reasons given for relinquishment for cats and dogs appear to be aggression, house-soiling, failure to integrate with other **pets**, destructiveness, hyperactivity and undesirable vocalization, most of which represent normal behaviours and reflect inadequate provision for the animal's needs.

Behavioural problems may also underlie other common reasons for surrender such as 'moving home', 'unanticipated demands' and 'changes in lifestyle'. In the case of horses, few data exist relating to the reasons for their surrender to shelters, but reasons tend to relate to owner circumstances (especially financial demands) and some sort of behavioural problem with the horse; a considerable number are released or abandoned on to open land, although requirements for mandatory registration may reduce this. Specific but widespread circumstances may result in bursts of abandonment for other reasons, for example, following natural disaster, such as the aftermath of Hurricane Katrina in 2005, which resulted in widespread animal abandonment as some rescue services would not take animals. Indeed there are some reports of people dying as they refused to evacuate without their pet. Other circumstances leading to an increase include: (i) media coverage over actual or potential zoonotic diseases such as rabies or avian influenza, resulting in relinquishment of dogs and parrots, respectively; and (ii) legislative changes in relation to the ownership of particular animals, e.g. the introduction of owner licensing fees or more stringent ownership requirements in relation to so-called 'dangerous' species or breeds. Abandonment is a serious cause for concern relating to the **welfare** of

companion animals; for example, in the USA it is estimated that approximately one-quarter of dogs pass through a shelter at some time and that just under half of these are surrendered directly by their owner. The rest are obtained as strays, with around 15% reclaimed. It is estimated that about 60% of shelter dogs are euthanized in the USA (approximately 2 million per year). Long-term maintenance within a shelter is an obvious cause for concern but, even for those that are successfully rehomed, the experience of passing through a shelter is inevitably stressful and in some cases may result in long-term behavioural and emotional disturbance.

The abandonment of animals does not relate just to the relinquishment of care towards companion and domestic species, but may also relate to wild animals that come under the care of people to a greater or lesser degree and for variable periods of time. This includes the abandonment of animals within a wild **animal sanctuary** or managed reserve (perhaps as a result of local conflict or lack of funds), which may result in a resurgence of poaching, as has occurred in the case of mountain gorillas in Rwanda. The abandonment of rabbits and edible snails, neither of which is originally native to the UK, may be considered as the cause of their naturalization within this nation. They were originally brought to the UK by invaders (Normans and Romans, respectively), who used them as a convenient food source (see also: **Exotic species invasions**). Also pest species, which are caught in so-called 'humane traps' that do not kill the animal concerned, could be considered as coming under the temporary care of a human who becomes responsible (physically and possibly morally) for the consequences for this animal. The release of this animal 'into the wild' may then be considered an act of abandonment, especially since the domestic setting may be a more appropriate environment for this species than a field with predators, etc. (see also: **Pest control – ethics of**; **Pest species – welfare of**).

Many of the common medium- to large-sized companion animal species (i.e. cats, dogs, horses) that are abandoned can survive and may breed successfully if given the opportunity to live outside captivity, as long as they do not have traits dependent on human intervention (e.g. coats requiring extensive grooming, assistance with giving birth due to anatomical extremes, etc.), since they are tolerant of a wide range of environments. The abandonment of animals is therefore one reason why an animal may become **feral**. Smaller animals and ectothermic species may face problems, especially with **thermoregulation** at cooler times of year in regions with markedly different (wetter and/or cooler) weather patterns; and even abandoned indigenous species (e.g. mice in the UK) may fail to survive and be subject to a higher risk of predation, due to both physical (e.g. coat markings that inhibit

camouflage) and behavioural (e.g. poor **predator avoidance** behaviour) characteristics.

Welfare problems also arise when animals are abandoned but confined, and so given less opportunity to adapt (**see also: Confinement**). Such confinement may be by means of some kind of tether or enclosure, such as a fence or the walls of a building, and typically will result in starvation or dehydration.

In many countries legislation in relation to abandoned animals exists. This legislation may relate directly to control over the act of abandonment or the control of animals who have escaped or been abandoned into the general environment (stray animals). The former emphasizes the responsibility of citizens to animals under their care, while the latter is often aimed at protecting citizens from the harm that may be caused by them (e.g. injury from a bite or road traffic accident). In some countries/regions abandoned animals are taken into care, under the responsibility of the police or a regional authority, for a short period before being euthanized if an owner cannot be found, but in others **euthanasia** may not be allowed and the animals must be cared for in the long term. This can be problematic because available space may become limited and the welfare of animals kept in such environments may in itself be seriously compromised. A key component to the enforcement of legislation relating to the abandonment of animals is the identification of the legal carer, and this too can be problematic without a requirement for legal identification of an animal and its ownership.

While abandonment is often considered a permanent or long-lasting act, the term 'abandoned animal' is also used occasionally in relation to a temporary absence of responsibility, e.g. the 'abandonment' of animals in cars during hot weather. (DSM)

Abnormal/abnormality

The concept of normality and abnormality is widely used in reference to animal behaviour and **welfare**; for example, in the **five freedoms** and the 'Codes of Recommendations for the Welfare of Livestock' (**see: Codes of practice**) it is stated that domestic animals should have the opportunity to perform most normal patterns of behaviour. However, it is less clear what this means and what is acceptable in practice.

While behaviours vary according to context, animals also have species-specific behaviour patterns that have an element of consistency, and abnormal behaviour may be considered that which deviates from this standard. This poses the problem of recognizing the standard being used, the behavioural measure (pattern of behaviours, individual form, intensity, functionality, etc.), its level of deviation, as well as its context must be defined. In many instances the term abnormal is simply used to describe behaviour that is rare (literally away from the statistical norm), but in these circumstances it must be recognized that there is not necessarily a link between the abnormality of a behaviour and animal suffering. In other instances the functionality of the behaviour may be used as the reference for normality, but in this case the term 'functional' is to be preferred to 'normal', as it is less likely to infer a link with an animal's welfare. For example, stereotypic behaviour (**see: Stereotypes**) might be considered abnormal because it is generally not seen in wild, free-roaming animals. However, if polar bears in captivity are considered as the reference point,

then when using a statistical approach it might be argued that it is not abnormal because it occurs quite frequently in this context.

In psychology, the concept of 'social deviance' is sometimes applied to assess the abnormality of a behaviour. This involves assessing the impression of other people of the behaviour and the impact that behaviour might have on them. One major problem with this approach is that it depends on the subjective opinion of the person using the term. The philosopher Wittgenstein has argued that many concepts have a similar problem of definition. Things that belong within a given category have certain resemblances without necessarily sharing the same features, like members of a family. All of the underlying defining features that make up the concept of abnormality need to be identified, and then simple assumptions about the link between the concept and its implications questioned. Seligman *et al.* (2000) propose seven criteria that might be used when referring to something as abnormal. These may be adapted to the field of animal behaviour thus, but the different usages have different implications for assessing the welfare of the performer:

1. **Suffering.** Behaviours related to suffering may be divided into those that cause harm to the performer or another, those that are associated with an attempt to adapt or cope with a suboptimal environment and those associated with an inadequate or noxious state, e.g. signs of frustration.
2. **Maladaptiveness.** This refers to the failure of a behaviour to fulfil its goal at either an **appetitive** or **consummatory** level, e.g. a failure to achieve **homeostasis**. Maladaptiveness may also refer to suboptimal behaviour, e.g. the ingestion of a non-nutritive foodstuff.
3. **Unconventionality.** This refers to the statistical rareness of a behaviour in a given context (**see definition above**).
4. **Unpredictability.** It is often implied that behaviours that cannot be predicted are abnormal because there is no recognized control of the behaviour. However, spontaneous behaviour is a rare occurrence and more often is a reflection of the knowledge of the reporter of the behaviour. Once the occurrence of a behaviour can be explained, it may cease to appear abnormal. For example, an owner who cannot predict their dog's aggression may describe it as abnormal, although a clear stimulus may be discerned by a therapist.
5. **Incomprehensibility.** Similarly, if the nature of a behaviour cannot be understood it may be described as abnormal until it is explained.
6. **Observer discomfort.** If a behaviour causes concern to its observer for any reason, although the reason for this should be given and justified, then it may also be described as abnormal on this basis. For example, some people may consider homosexual behaviour offensive and so describe the behaviour as abnormal.
7. **Violation of standards.** Standards may be set which, if they are not met, may classify a behaviour as abnormal. For example, there may be an expectation for a given behaviour not to occur, such as aggression in horses towards people, so its occurrence is abnormal by definition, even if it can be understood.

Many of these criteria are subjective, but still they encapsulate the essence of how the term 'abnormality' may be

used. Any behaviour described as abnormal may meet one or more of these criteria in a given context. It is important that any link to welfare is demonstrated logically and not inferred by virtue of the use of the term 'abnormality' of the behaviour alone. Just because a behaviour fulfils one of these criteria, it does not infer that it fulfils any other, i.e. abnormality is not necessarily a welfare problem. (DSM)

Acetylcholine

Acetylcholine (ACh) is a neurotransmitter that occurs widely in animals, being found throughout the somatic nervous system, but less ubiquitously within the **autonomic nervous system**. Acetylcholine is stored in vesicles within nerve endings and then released through exocytosis in response to an action potential. It is cleared from the synapse largely as a result of the enzyme acetylcholinesterase. Smooth and skeletal muscle respond to ACh by contracting, while cardiac muscle will relax. Acetylcholine is released by the terminal nerves of the **parasympathetic nervous system**, while **epinephrine** is released by the terminal nerves of the **sympathetic nervous system**. It is therefore associated with derousal. Centrally, ACh release facilitates both learning and short-term memory at the cellular level, and it is involved in both top-down and bottom-up **attention** processes; it is also involved in the scheduling of **REM sleep**. Two general types of ACh receptor are recognized, muscarinic and nicotinic, on the basis of other chemicals that also stimulate these receptors (muscarine and nicotine). (DSM)

ACTH (adrenocorticotrophic hormone)

ACTH is the abbreviation for adrenocorticotrophic hormone. ACTH is a 39-amino-acid peptide hormone produced in the anterior **pituitary gland**. Production of this hormone is stimulated by corticotropin-releasing factor (CRF) which travels from the **hypothalamus** through the blood to bind to receptors on corticotrophic cells of the anterior pituitary. Activation of these receptors then causes the production of **pro-opio-melanocortin**, referred to as POMC. Enzymatic cleavage of POMC in the anterior pituitary gland forms several hormones, including **beta-endorphin**, melanocyte-stimulating hormone and ACTH.

ACTH is released into the peripheral vasculature, which allows it to travel to the cortex of the adrenal gland to bind to receptors, causing the production of **glucocorticoids**. The predominant glucocorticoid in cattle, swine and sheep is cortisol, whereas in poultry and rodents the predominant glucocorticoid is corticosterone. The release of glucocorticoids causes the liver to produce glucose (gluconeogenesis).

ACTH production and excretion is controlled by the negative feedback effect of glucocorticoids on the anterior pituitary gland to directly decrease ACTH synthesis and excretion. Glucocorticoids also have a negative feedback effect on the hypothalamus to decrease CRF synthesis and excretion.

Because ACTH plays a dominant role in increasing energy availability in the form of glucose, it has been considered of major interest in terms of how animals cope with and respond

to environmental challenges and **stress**. Stress research has long focused on the concept of the 'fight or flight' response which requires that the animal has rapid availability of energy (glucose) to mount a response to a threat. Therefore, researchers have used the measurement of ACTH and its associated activation path to measure a response to stress. One such test is the ACTH challenge test (ACTH stimulation test), which involves injecting ACTH to stimulate the adrenal gland to release glucocorticoid. Researchers can then measure the circulating concentrations. The reason that this test may show when an animal is stressed is because under chronic stress, the adrenal gland of animals enlarges due to hyperplasia and hypertrophy. This enlargement enables the animal to produce more glucocorticoids. When given ACTH the circulating concentrations of a chronically stressed animal should be greater than an animal that is not stressed. Thus, circulating glucocorticoids can potentially give us a quantitative measure of the level of stress an animal is experiencing, although there are limitations to its interpretation and usefulness. (DCL)

Adaptability

Adaptability describes the extent to which the regulatory systems of an animal can facilitate physiological or behavioural responses that allow it to deal with changes in its environment. The adaptability of an individual depends not only on its health, age and status but also on the type and degree of that environmental change. (KT)

See also: Adaptive; Coping; General adaptation syndrome; Homeostasis

Adaptive

Behavioural and physiological traits that have been preserved by **selection**, because they offer a **fitness** advantage to individuals that carry the genes for their expression, may be said to be adaptive. This includes traits that increase the individual's ability to reproduce – for example, a successful mating strategy or attractiveness to the opposite sex. It also includes traits that increase the individual's ability to survive – for example, traits that enable an individual to find food or cope with changes to its environment.

Adaptive behaviours are not just those that have been selected for genetically during the evolutionary history of the species because they confer a fitness advantage to the individual in the environment in which the species evolved; behaviours may also be transmitted between generations as a result of cultural transmission (**see: Social learning**), for example, the deliberate action of moving into water or higher pastures by feral horses to escape airborne parasites. With time such traits may acquire a genetic basis.

The adaptive value is the increase in fitness that a physiological or behavioural trait confers on an individual, relative to the cost to the individual of having this trait. If a trait confers a large advantage on the individual in terms of survival or reproduction and at little cost in terms of energy or risk of reduced fitness, then that trait can be said to have a high

adaptive value. Traits with high adaptive value are more likely to be preserved within the gene pool.

Adaptive intelligence is the ability to solve problems as a consequence of previous experience with similar problems. If a problem is encountered frequently enough the individual has more opportunity to learn the best solution and apply this to other, similar, situations. This ability to learn is an adaptive response because it helps maximize the animal's fitness. (KT)

Adoption

The young of many species depend upon the care provided by one or both parents to survive. In some species, individuals other than the genetic parents provide a portion of care, a phenomenon known as **alloparenting**. Adoption is an extreme form of alloparenting, in which an individual other than the genetic parent provides all (or nearly all) care for the young.

Adoption in nature is generally rare, although it has been reported anecdotally in hundreds of avian and mammalian species. The evolution of any behaviour depends upon how that behaviour ultimately affects an individual's ability to survive and reproduce (direct fitness) or have a positive impact on the survival and reproduction of its relatives (indirect fitness). In order for a behaviour to become widespread in a population, the fitness benefits of performing that behaviour must exceed its costs (**see also:** **Optimality**). Adoption involves many potential fitness costs to the adoptive parent, such as: (i) energy; (ii) increased exposure to predators; (iii) loss of the opportunity for producing its own young or decreased ability to care for existing descendent young; and (iv) the fitness benefits are usually minimal unless the adopted individual is a relative.

Usually, adoption appears to be the result of misdirected **parental behaviour**. While it might be theoretically possible for caregivers to discriminate fairly accurately between descendent and non-descendent young, any such discrimination mechanism would carry a risk that a parent would mistakenly deny care to its own offspring. In an evolutionary context, being responsive to offspring and exhibiting proper caregiving behaviours are so important that they often outweigh the cost of providing care to non-descendent young.

The value of a precise discrimination mechanism increases with the increasing likelihood that a caregiver will encounter non-descendent young. Thus colonial, synchronously breeding species with precocial (and therefore independently mobile) young tend to have more highly developed discrimination mechanisms than those that breed in isolation. In practice, rather than showing a precise ability to discriminate, most species use 'rules of thumb' in providing parental care. These rules of thumb are often based on spatial criteria ('provide care to any young in the nest') or familiarity ('provide care to the young that were encountered immediately after parturition').

One type of adoption, termed brood parasitism, has evolved many times in nature. In brood-parasitic species such as wood ducks, mothers provide care to any young that are in the nest and have limited ability to discriminate between individual young. This type of rearing system is vulnerable to exploitation by conspecific females that deposit eggs surreptitiously in the nest, leaving the nest owner to raise the hatchlings. Another form of adoption occurs in several colonial bird species (e.g. emperor penguins, kittiwakes, ring-billed gulls, Alpine swifts). In these species, the precocial young themselves move between nests, abandoning their natal nest to join one that is less infested with parasites or that contains younger, smaller nestlings that they can dominate.

In mammals, adoptions are very rare but it is possible to make some generalizations based upon anecdotes. Two factors seem to precipitate adoption events. First, orphaned or abandoned infants can be very persistent in soliciting care from other females that they encounter. Secondly, females that have given birth to stillborn young or whose young die shortly after birth will still experience the powerful surge of hormones that triggers the onset of parental care and facilitates parent-offspring **bonding**. This can cause them to behave maternally towards non-descendent young and, in some cases, leads to the adoption of an orphaned or abandoned infant. Most cases of adoption involve females that are already lactating, but the sensory stimulation associated with suckling can, in some species, induce lactation in a female that has not recently given birth. The highest likelihood of adoption is expected in species where females live in kin groups, because adoptive mothers would increase their inclusive fitness by rearing an orphaned relative.

While adoption is clearly not an artefact of **captivity**, it does appear to be more common in captive settings than in nature. This may simply be because reproduction and infant rearing are more closely observed in captivity. Additionally, specific aspects of the captive environment, such as enforced spatial proximity or enhanced reproductive synchrony, may facilitate adoption. Captive animals are generally more likely to show aberrant parental behaviours, which increases the chance that an infant will be abandoned or neglected by its genetic mother.

The existence of adoption in nature can have useful implications for animals in laboratories, zoos or other captive settings. The lack of a precise ability to discriminate between descendent and non-descendent young can enable the **fostering** of young between different females for reasons of experimental design or to equalize brood or litter sizes. Captive managers may also enhance the survival of offspring born to individuals with infanticidal tendencies, by removing them from their parents and fostering them to individuals with proven parenting skills. Additionally, it may be possible to increase reproductive rates in genetically valuable individuals by fostering their offspring to be raised by less genetically valuable individuals, thereby allowing the valuable individuals to re-breed sooner. It is important to recognize that among species (and among individuals within a given species) the degree of tolerance to non-descendent young can vary along a continuum from highly tolerant to infanticidal. For those that show tolerance of non-descendent young, adoption provides another option besides **hand-rearing** for orphaned or abandoned young. To capitalize on this opportunity, adopted

young must be closely monitored to ensure that the adoptive mother is providing adequate care to both the adopted infant and any current dependent young. (KVT)

Adrenal gland

The adrenal glands are a set of paired organs located beside the kidneys. They are comprised of an outer portion – the cortex – and an inner portion – the medulla. The adrenal cortex is comprised of three layers and produces **glucocorticoids** and mineralocorticoids. The adrenal medulla is a modified ganglion and, upon stimulation of the **sympathetic nervous system**, produces **epinephrine** (adrenaline) and **norepinephrine** (noradrenaline). (DCL)

Aetiology

Derived from the Greek word *aitios*, meaning cause, origin or reason, aetiology is the study of causation. As applied to animals, aetiology refers to the cause of a disease, disorder or behaviour. If the aetiology of a disease or disorder is unknown, the causal factor(s) have yet to be identified and may therefore be called idiopathic. (KT)

Affiliation

The evaluation of affiliative behaviours has underpinned a large proportion of the research into the social complexity of many social species, particularly non-human primates. Affiliative behaviours are often termed ‘positive interactions’ and, within the primates, can include **grooming**, physical contact and infant care. Social grooming is one of the most widely used measures of affiliative interactions in the studies of social relationships.

However, other affiliative behaviours are exhibited by social species, e.g. the spotted hyena (*Crocuta crocuta*) demonstrates a number of behaviours that can be termed affiliative, including mother–infant attachment and social play. In addition, hyenas demonstrate ritualized greeting ceremonies as a means of advertising and reaffirming social relationships. As hyenas have a **fission–fusion society**, individual clan members may spend significantly long periods of time in isolation. Greeting ceremonies facilitate the constant transition from solitary to social status. Ritualized greeting behaviours usually occur at the communal den after a period of separation, although these behaviours have also been seen in other social circumstances. Animals of either sex will stand head to tail with legs lifted in reciprocal presentation of the genitalia and anal scent glands. Virilization of the female genitalia in the spotted hyena allows both sexes to engage in erect phallus display. In accordance with a strict social etiquette, subordinates will always lift their legs first.

Affiliative behaviours can apply to a variety of social models, including **reciprocity**, altruistic behaviours, reconciliation and consolation, and can be affected by kinship, dominance hierarchies, familiarity, etc.

Reciprocity

In many mammal species affiliative behaviour is directed towards particular classes of individuals. Although developmental research has shown that many preferences for partners in affiliative behaviour will emerge during infancy, these preferences may play an important role in determining group affiliation patterns at a later stage in life. Age, gender, kinship and social status can play important roles in the development of these group affiliations. Changes in female reproductive status have also been seen to override and alter some of the affiliative bonds in non-human primates.

In non-human primates kinship is recognized as a significant determinant of affiliative relationships, particularly in levels of grooming behaviour and proximity. In many female **philopatric** species female grooming is significantly more kin-oriented than male grooming. This kin bias for affiliative behaviours can assist in the establishment of **matrilines** (particularly in macaques, *Macaca* spp.). Matriline can have a strong influence on group behaviour, including feeding patterns and group travel. Females with a strong matriline can rely on support from their kin in social contests and will often hold a dominant position within the group. Matriline can also have a strong impact on the hierarchy positions of individual animals. Several species of Old World monkeys have dominance hierarchies in which individuals within a matriline occupy adjacent ranks, and their offspring often acquire a rank just below that of their mothers. This close mother–infant bond can then be maintained (and reaffirmed through affiliative behaviours) into later life stages.

Dominance hierarchies describe relationship patterns between animals that engage in repeated social encounters, particularly where status is not necessarily predictable from physical characteristics. Social rank and dominance hierarchies can be seen to interact strongly with kinship in the distribution of affiliative behaviour. High-ranking individuals generally groom at a far lower rate and receive grooming at an increased rate in comparison with lower-ranking individuals. Grooming may be most commonly seen between closely ranked and closely related females.

The distribution of grooming within a primate group can also be strongly influenced by the reproductive status of the females within that group. Seasonal breeders will become the focus of increased grooming behaviour from males (i.e. will receive higher levels of grooming) in the breeding season. Even in non-seasonal breeders the oestrous cycle and the formation of consortships can lead to higher levels of grooming behaviour. In this situation it has been suggested that increased grooming behaviour reduces the risk of **aggression**, allows the increased proximity necessary for mating to occur and can temporarily impact on social status within groups. This has been observed in hamadryas baboon harems, where females in oestrus give higher levels of grooming directed towards the alpha male while receiving higher levels from the male, and have been observed to ‘leapfrog’ positions within the female hierarchy.

Altruism

Social grooming can be seen to fit the definition of altruistic behaviour, as it appears to incur greater costs than benefits to the recipient. The costs involved in a grooming bout include

expenditure of time and energy and the reduction of time available to engage in other necessary activities (i.e. feeding, vigilance behaviours). However, the benefits of grooming can be more difficult to define. In some cases it may appear that groomers may derive protection from the groomed animal, or it could be considered to be a reinforcement of dominance ranks between individuals. It seems likely that the benefit received by the groomer is social tolerance, so that a low-ranking animal grooming a higher-ranking animal is able to maintain proximity and thereby some level of protection or sharing of resources. However, there is a lack of easily interpretable data on a casual relationship between affiliative behaviours (such as grooming) and agonistic support, partly because these interactions often occur at a low rate and can be separated by long time intervals. Tolerance may not be the only benefit to a grooming exchange. Evidence of grooming exchange for sexual favours, food and access to infants has been identified.

Although grooming tends to be heavily biased towards kin selection, grooming between non-kin is often thought to be maintained through grooming reciprocity, where the reciprocation can be either in the same currency (reciprocity) or in a different currency (interchange). Early studies indicated that grooming between non-kin in stump-tailed macaques was usually reciprocated once grooming had been initiated, although conflict over which member of the dyad would initiate grooming was not unusual. However, most individuals did appear to attempt to maximize grooming received while performing as little grooming as possible. In addition, grooming levels between familiar and non-familiar animals can be seen to vary greatly. Interactions between familiar cage-mates demonstrated a high level of affiliative behaviours, whereas non-familiar individuals tended not to reciprocate. These interactions were categorized by a high level of grooming solicitations that were not followed by grooming bouts. This suggests that grooming between non-kin follows strategies of reciprocation such as 'tit for tat', in which the cooperative first move is followed by the individual either continuing or defecting, depending on their partner's behaviour.

In social systems conflicts of interest can arise between individuals within the group, most commonly competition for access to resources (i.e. food, mates). In these situations behavioural interactions may escalate into aggression which, in turn, may compromise the benefits of group living or future cooperation between the opponents. Behavioural mechanisms that may work to prevent aggressive escalation can be strongly selected for in social animals; however, there has been very little research focused on this particular area to date. In comparison there is a growing body of research on behavioural mechanisms following escalated aggressive incidences, particularly the use of affiliative behaviours for both 'reconciliation' and 'consolation'.

Reconciliation

Initial research into this phenomenon with captive chimpanzees indicated that opponents in an aggressive conflict spent more time in close proximity and exchanging friendly behaviour than before the aggressive incident. This has been termed 'reconciliation' and can be viewed as a mechanism to repair social bonds that have potentially been damaged by

aggression. The vast majority of research into reconciliation has been undertaken with primates in captivity, where it has been argued that limited enclosure sizes can create an artificial social environment. This has led to the suggestion that reconciliatory behaviour may in fact be an artefact of the captive environment. However, research carried out in large enclosures where prolonged avoidance of individuals is possible and research with habituated wild primate groups both suggest that reconciliation does occur outside of the captive environment, although possibly at lower frequencies.

In species that tend to show high conciliatory tendencies, reconciliation can involve behaviour patterns that can be termed affiliative but are rarely seen in other contexts (explicit reconciliation). In other species regularly observed affiliative behaviours such as grooming or physical contact can be seen to have a reconciliatory function; for example, in a number of species (hyenas, *Crocuta* spp. and baboons, *Papio* spp.), ritualized greeting ceremonies (such as that described above for hyenas) are thought also to serve a reconciliatory function in conflict management. In this case the affiliative behaviour may provide a means of repairing social relationships and achieving a balance with aggressive behaviour.

The recognition of reconciliatory behavioural patterns within a range of species has assisted with the classification of 'dominance styles' within species; 'despotic' species (rhesus macaques, *Macaca mulatta*) are relatively aggressive, have steep power gradients and reconcile fewer conflicts. In comparison, 'tolerant' species (Tonkean macaques, *Macaca tonkeana*) typically display low-intensity aggression and high levels of affiliation and reconciliation. Only the tolerant species have been seen to exhibit explicit gestures for reconciliation, although this has also been seen to vary between groups of conspecifics.

Consolation

'Consolation' has been defined as any increase in affiliative interaction between targets and third parties specific to post-conflict contexts, although it is perhaps best reserved for those interactions initiated by third parties. This raises a further question as to whether these interactions may then have been triggered by 'empathy' on the part of the third party. The major function proposed for consolation focuses on the alleviation of stress in a post-aggressive context and, potentially, protection from further aggression.

Factors influencing development of affiliative behaviour

Many developmental psychologists believe that the parent-infant relationship has a unique role in the socialization of the infant; however, an alternative view is that social development is mainly affected by the experiences within a peer group. Therefore, the acquisition and development of affiliative behaviours can be paramount to an individual's development. Research has indicated that individuals that are deprived of social interaction with peer groups may exhibit reduced social competence in adult life.

Research conducted with non-human primates has demonstrated clear gender differences in affiliative behaviours (particularly grooming and play), emerging early on in life. Female macaques will be both giving and receiving higher levels of grooming interactions by 2 to 3 years of age. Female-female

grooming increases steadily throughout the juvenile period to adulthood, with greatest emphasis being placed on the grooming of kin. Juvenile females will groom both older females and younger individuals until the onset of menstrual activity, when the grooming of males will begin to increase. Conversely, when macaque males are 3 to 4 years old, their grooming activity is significantly lower than that of the females and is not kin-biased. The majority of grooming interactions are directed towards the adult males; however, it is rarely reciprocated. Male–female grooming will increase with the onset of puberty and emigration from the natal group.

Gender differences are also prevalent in the amount of play and the types of play exhibited by young non-human primates. In most primate species after the first 6 months of life males will engage in higher levels of ‘rough-and-tumble play’ than most females. Juvenile males will also both initiate and accept invitations to play far more frequently than females. Juvenile and sub-adult males also demonstrate higher levels of social play and of a type that is more vigorous. Females will engage in higher levels of solitary play but, in addition, will also begin to demonstrate play parenting within the first years of life.

Affiliative play behaviour can also be influenced by kin effects. Infants with closely related and similarly ranked mothers will often engage in higher levels of play than those whose mothers are unrelated or have a large gap in rank.

Spotted hyenas have also been observed to engage in social interactions that can develop into play patterns from the early stages of life (as early as the second stage of life in captivity). By approximately 1 month of age cubs engage in more frequent bouts of rough-and-tumble play and can therefore be said to have a system of affiliation. This facilitates introduction to peers and clan members on transfer from the natal to the communal den. It has been seen that dominant hyena cubs will initiate play bouts more frequently than subordinates. During play bouts a dominant animal is more tolerant of contact (being knocked to the ground, gently mauled) from a subordinate.

In some primate species (i.e. gorillas, *Gorilla* spp., black howler monkeys, *Alouatta pigra*) strong affiliative relationships have been seen between infants and adult males. The infants will spend more time interacting with or being closer to the males than their own mothers and the males will hold, cuddle, nuzzle or groom the infants. These infants will often turn to the males in times of distress. The males are often very tolerant of infant play and will allow youngsters to climb and tumble on their backs. Baboon males have been seen to ‘baby-sit’ infants when the mother is absent, sometimes grooming or carrying the infant. Protection for the infant appears to be an important benefit for these affiliative interactions, with the adult males often acting as a buffer between the female–infant dyad and threats from conspecifics. Tolerance and food sharing between males and infants has also been seen in species exhibiting these strong affiliative bonds. In addition, for mountain gorillas it appears that male infants that establish a strong bond with the silverback (the mature male) and maintain it through adolescence are more likely to inherit leadership of the group, whereas those male infants that do not establish such a strong bond are more likely to emigrate from the group. These strong male–infant bonds are often accompanied by strong affiliative bonds between the male and

the infant’s mother, although they can also be influenced by male rank, dyadic preferences and infant needs.

Although most aspects of affiliative behaviours within non-human primates have been documented as intra-group social interactions, there are cases of inter-group affiliative interactions (play, grooming, touching). The primary proponents of these interactions are young males, although this is far from exclusive of the other age-classes. However, there is a lack of comparable data of the frequency of these interactions to be able to comment on this. (KP)

Ageing

An animal’s behaviour may change when it becomes aged due to: (i) nerve cell loss, reduced connections between nerve cells and other cellular changes in the **brain**; (ii) deteriorating perceptual function, as in the case of impaired vision and hearing; and (iii) impaired physiological changes separate from those occurring in the nervous system (e.g. arthritis, cardiovascular dysfunction).

Behavioural testing of dogs has shown that ageing slows learning, particularly spatial memory, and alters activity cycles, but there is so much variation between species and even strains/breeds that it is difficult to ascertain what might be considered as old age. Individual differences are also marked. Diet and life history can affect ageing. Aged rats housed in an enriched environment, allowing social interaction with other members of their species, have more connections between the nerve cells in their cerebral cortex than do rats housed in an impoverished environment in isolation. To a large extent our knowledge of ageing in animals is based on those species kept as pets and on a limited number of laboratory species used in research on ageing (rats and some species of primates). Aged dogs, 9 years old or more, show cell death (apoptosis) and senile plaques in the brain, and a behavioural test is available for scoring dementia in dogs: the degree of dementia correlates with the extent of apoptosis but is unrelated to the number of senile plaques. Many species of birds are very long-lived compared with mammals of equivalent weight.

According to one theory of ageing, the oxidative stress theory, which states that free radicals cause the degenerative changes in the brain, the longevity of birds is unexpected since they have higher metabolic rates than mammals and hence should be at greater risk of degenerative effects. This has led to the suggestion that birds may have a special protective mechanism against ageing. Other theories of ageing include: (i)

the neuroendocrine theory, with new evidence for a role of the cell growth and survival factor, IGF-1; (ii) the evolutionary theory of ageing, which considers the accumulation of late-acting DNA mutations; and (iii) the theory of telomere shortening, which concerns cell division. (LJR)

Aggression

Aggression is derived from the Latin word '*aggredi*' meaning 'to attack'. S.A. Barnett described aggression as 'a word with many meanings, and a source of much confusion', largely because it is used in very different contexts by biologists, psychologists, psychiatrists, sociologists and the media. The term has had an unfortunate tendency to have different meanings, even within the course of a single scientific article or review. Aggression is generally applied to the threat and attack components of **agonistic behaviour** in animals. In addition, it is actually a somewhat 'loaded' epithet, often implying that there is something excessive, inappropriate or undesirable about the severity and/or nature of the animal's responses. The term is especially problematic when applied to **companion animals**, where a behaviour may be welcomed in one context and disapproved in another, e.g. a dog barking at a stranger but not at the owner's partner. The basic problem is that aggression (because of its almost ubiquitous occurrence in animals) clearly serves biological functions but is often uniformly regarded as reprehensible in society (this is called '**negative apperception**' by some social scientists). Such activities clearly cause, however, problems in captive and domestic animals.

To qualify for the label 'aggression', it has been suggested an activity should:

1. Have at least the potential to cause injury or damage to another animal (often a member of the same species), with the focus generally being on physical injury rather than psychological damage. Consequently, elements such as biting, pecking, kicking, pushing, stinging and goring are usually stressed in descriptions of such behaviour in non-human animals.
2. Be deliberate or intentional (rather than accidental). It is difficult to establish this with any certainty in most cases.
3. Be **aversive** to the victim of attack or threat (such that the animal tries to avoid it). This is to eliminate some sexual displays in certain species from inclusion.
4. Be accompanied by arousal (evidence of internal activation in the form of increased heart rate, altered tissue distribution of blood, release of 'stress' hormones or elevated rates of breathing) in the aggressor (this would exclude many forms of predatory behaviour from the definition, as they often lack this

characteristic). Most studies attempting to assess arousal do not directly measure internal physiological changes but rely on 'body language' such as piloerection and positions of the ears in cats and dogs, as well as tooth exposure in primates.

None of these characteristics, on its own, is sufficient for firm characterization of a response as being 'aggression'. Conversely, there are many examples of activities with one of the above attributes that clearly do not constitute aggression in most schema.

The entire range of available animal senses may be employed in expressions of aggression. Visual examples include the wide use of characteristic postures, but also other bodily features, such as: (i) the red abdomen of the territorial male three-spined stickleback (such seasonal changes are not limited to this fish); (ii) the comb and wattles of the domestic chicken (their size and brightness reflect the animal's social status); (iii) the black patches on the chests of female golden hamsters (the larger, the more dominant the animal); and (iv) the antler displays of red deer (these annually produced structures increase in size and complexity with maturity).

Examples involving **olfaction** include the use of **urine** and faeces in territorial marking in dogs and cats (this can be regarded as a 'problem' behaviour), but also in many rodent and ungulate species (this is one reason why attention should be paid to the cleaning of cages and enclosures).

Examples involving **audition** (i.e. the production of particular sounds) include: (i) croaking by frogs and toads (pitch is often an indication of the animal's size); (ii) rattling by the rattlesnake; (iii) 'roaring' in rutting red deer stags; and (iv) a range of bird and primate calls. Certain species use sounds at frequencies below (infrasound) or above (ultrasound) human hearing. Other species may use other senses such as touch (including pressure waves in water by fish) and even electromagnetic communication (e.g. in some electric fish). Clearly, understanding aggressive displays implies also understanding the sensory systems employed by particular species. Most species use a range of sensory communication in their displays.

The above types of **communication** may enable the animal to succeed using threat alone, as overt fighting can be damaging (see later) and generally only occurs *in extremis* or if individuals are equally matched in competitive ability. Even if it does not result in injury, aggression is very energetically demanding. The constraints of captive housing may render threat a less effective means of avoiding conflict, as it is difficult for animals to remove themselves from the vicinity of the potential aggressor.

The term 'aggression' has been applied to a very heterogeneous set of phenomena, being used as an epithet for activities as diverse as 'spontaneous' fighting in wild and captive animals to subjects biting their handler or another species. This can be illustrated by the very wide ranges of rodent models of aggression (but other species, e.g. dogs and deer, also show similar diversity) repeatedly employed in the laboratory. They include:

1. Social conflict, where threat and attack (generally in encounters between members of the same species) are used to compete for a resource, the winning of which increases the victor's relative **fitness** (breeding potential). Such conflicts

often employ strategies ('ritualization') that minimize the potential for serious damage, e.g. by avoiding bites to vulnerable areas of the opponent's body (this is important as all animals are vulnerable to defeat at some stage in their lives). Social conflict is expressed differently in varied animal species (and one should not assume functions by extrapolation from other species). In some animals (e.g. red deer) the conflict is used by males to compete for mates (a harem). In a smaller number of species, females fight for males. In others, fighting and threat are used to delineate a defended area or territory (e.g. the European robin). In others (e.g. domestic chickens and many primate species) the behaviour determines an animal's status within a social hierarchy (e.g. a 'peck order'). Some individuals directly compete for food that is necessary to 'fuel' their reproductive efforts as well as behaviour in general.

2. Parental defence, where threat and attack between members of the same or two different species are used to protect either the attacker's young or nest sites from potentially destructive intruders. For example, lactating mammals will often attack intruders coming near their offspring.

3. Self-defence, where threat and attack between members of the same or two different species are used to protect the 'aggressor' from potential predators or attacking members of their own species. These behaviours are generally only seen *in extremis* if flight or escape is precluded (as is frequently the case when caging is used or if an animal is suddenly cornered). They involve no injury-limiting ritualization strategies and attack can be especially damaging.

4. Infanticide involves the killing of (generally) unrelated young. In males, this strategy seems to be a method of increasing the individual's reproductive fitness (as it facilitates the attacker's reproduction), whereas in females of some species it may be a device for reducing litter or clutch size to manageable proportions.

5. Predation may occur within a species (cannibalism) but often involves different species. It often is characterized by an efficient killing strategy (prey can be dangerous to the attacker) and is generally followed by feeding activity. In laboratory rodents, mouse-killing behaviour by rats and insect killing by mice and hamsters have been the most studied examples of such phenomena. Many workers regard predation as being very different from more accepted types of aggression (notably because of the general lack of emotional arousal), but killing (e.g. by domestic cats of garden birds) can be regarded as problematic 'aggression'.

Structure of aggression

Aggression seen in different situations clearly serves a variety of functions, particularly offence, defence and predation. Having said this, the idea that an individual's behaviour can be classified as 'purely' offence or defence is not supported by experience. An individual's motivation generally changes over the course of an encounter (e.g. from dominant to submissive in the case of a defeated animal). The diversity of 'aggressions' in humans is even greater (largely because of the inclusion of their verbal and written responses). Although many of the human examples are unlikely to have parallels in non-human animals, there is a tendency in the media to assume that aggression has similar meanings in the biological and social sciences. As noted earlier, this causes further confusion.

All forms of aggression are products of complex interplay between:

1. Biological factors such as genes, particular neural circuits, neurotransmitters and hormones, etc.
2. Situational determinants, namely the context in which the animal finds itself (e.g. encountering a competitor in its home cage).
3. Experiential influences acquired as a result of the animal's accumulated positive and negative experiences in previous conflict situations.

It is not easy to separate these elements. The diversity of the concept means, however, that there will be no single physiology of aggression, i.e. all forms of threat and attack cannot be linked, for example, to the Y chromosome or to **androgens** (the view that aggression is a 'male' attribute is mistaken). Hoping to find simple 'cures' by **castration** or the use of psychoactive drugs for problem behaviours is unduly optimistic. Situations even within the same species have to be considered on a case-by-case basis.

Factors affecting aggression

Genotype has a strong impact on social aggression (an expression of threat and attack that is important in animal **welfare** terms). Different lines or strains of animals (from mice to dogs) may show considerable variation in their aggressiveness (the ease with which they display threat and attack).

Individual housing (see also: **Isolation**) is generally accompanied by increased aggressiveness in the males of a variety of laboratory rodent species, including many mouse lines, rats, the guinea pig, the deer mouse (*Peromyscus* sp.) and the Mongolian gerbil. The majority of social organizations recorded within groups of male mice in small cages are despotic dominance relationships, where one animal is dominant to a group of equally ranked subordinates (this may actually suggest that male mice are not notably social animals). There are, however, as in the peck order of chickens, linear hierarchical organizations in some social species. Attempts to 'environmentally enrich' captive animals often involve providing opportunities for social interaction with conspecifics. Having said this, the aggression seen in some groups (especially if the species is not notably social, e.g. polar bears) may be a source of concern or even be linked to **stereotypies**. Social grouping is not uniformly beneficial and each situation has to be considered on a case-by-case basis. Even stable groups need consistent monitoring for conflict.

Breeding experience (with separation from other mature males) induces a propensity to attack in males of some species (e.g. mice). This may reflect the common use of territorial behaviour for breeding activity by males. There is substantial evidence that the presence of females increases aggressiveness in males and that pregnancy/lactation may be associated with reduced tolerance by females of strangers.

The practice of replacing the sawdust substrate regenerates fighting in males of established social groups of mice. This temporary increase may be a consequence of disrupting the patterns of odour marking used in this species. Obviously, cleaning of captive animals can have important effects on their displayed aggression. Some small primates may be prone to similar problems.

Familiarity with the test situation (e.g. a 'home cage') in many animals may increase the probability of seeing fighting. Furthermore, familiarity with particular partners tends to reduce aggression ('strangers' are most likely to be attacked). Repeated experience of defeat and success in fights generally, respectively, reduces and increases subsequent threat and attack.

Cage design (e.g. the siting of feeding and watering locations) can have profound effects on fighting behaviour in captive animals. Dominants may exclude subordinates from these essential resources and cause them serious difficulties.

Consequences of aggression

Obviously, overt aggression can cause serious tissue damage. As well as reducing or suppressing a defeated or subordinated individual's reproductive activity (there is evidence in groups of some species that most of the breeding is performed by dominant or territorial individuals), the 'stressful' effects of fighting (and especially defeat) have other deleterious actions. Fighting associated with 'crowding' increases the retention of introduced endoparasitic larvae in mice. Furthermore, the hormonal correlates associated with 'social stress' may slow the antibody response to challenge with standard antigens. Such changes may account for the often-recorded reductions in disease resistance in defeated or subordinated rodents. The 'stresses' generated by fighting may also have detrimental effects on the functioning of particular organ systems, e.g. these can produce chronic and irreversible hypertension accompanied later by arteriosclerosis and nephritis. It is interesting, in this respect, to note that ACTH damages the Bowman's capsules in the kidney. Blood urea levels (indicative of kidney damage) are elevated in 'free range' territory holders and subordinates compared with dominant and subordinate mice from stable groups.

Consequently, the generation of **social stress** by aggression is a complex phenomenon with wide-ranging repercussions. Although the traditional association between hormones and fighting has been emphasized, other aspects of physiology should also be related to much wider descriptions of behaviour. Although the stress generated by conflict can acutely cause considerable problems leading to injury (e.g. wounding, breaking of limbs, blinding, etc.), failure to gain weight at a normal rate and reduced fitness in laboratory rodents, there are husbandry steps that one can take to ameliorate the effects of social conflict. Similar steps can be taken for farm and zoo animals, but the precise programme would depend on the species, the strain, the age of the subjects and their prior history.

Hormonal variations (however produced) clearly modulate the behavioural characteristics of animals and change the individual's production and detection of social signals. The relation of these factors to aggression is clearly very complex, involving actions at different stages of the animal's life.

The experience gained with rats and mice might well help guide the necessary pioneering investigations on the effects of social stress in farm animals by workers on both chickens and pigs. Control of aggression is also something that is essential for persons involved in captive breeding programmes in zoos and elsewhere. We have to accept that these 'undesirable' behaviours are rooted in the animal's basic biology, having had

survival value in the wild progenitors of captive animals. Understanding the origins of and controlling the factors involved in aggression are the best means of generating solutions to the deleterious consequences of this activity. (PFB)

Aggressive behaviour

Behaviour may be referred to as being aggressive or a form of **aggression** if it is considered by an observer that it may cause harm to another. This has led to considerable confusion over the definition of aggression, with some authors classifying elements of behaviours such as **play** and **predation** alongside components of agonistic interaction and responses to **frustration** as different 'forms' of aggression (play aggression, predatory aggression, competitive aggression, etc.). However, play and predation relate to qualitatively different functional processes and types of **arousal**. This has led some to describe the hostile behaviour that occurs in association with arousal within an **aversive** situation (such as in response to frustration or perceived threat) as affective aggression, in order to distinguish it from the states related to play and predation. It can be argued that the use of the adjectival derivative is preferable in relation to play (i.e. 'aggressive play') and that the term aggression be deleted in relation to predation in order to avoid inadvertently implying that these behaviours are mechanistically related to each other or to affective aggression. (DSM)

Agonistic behaviour

Agonistic behaviour is classically defined as being any behaviour that is associated with conflict and competition – including attack, escape, threat, defence and **appeasement**. **Aggression** or **aggressive behaviour** is an integral part of agonistic behaviour, but the two terms should not be used synonymously. Most animals kept by man as companion, laboratory or farm animals are social animals – ordinarily existing in **social groups**. Agonistic behaviour can occur between members of different groups and between members of the same group.

From an evolutionary standpoint, group living confers a number of benefits (as well as costs). A group is likely to be more efficient at detecting, acquiring and defending food (or other resource). It can detect and defend against predators and, when confronted by a predator, the chance of an individual within a group being predated is much less than if the individual were confronted alone. A group can be better at surviving cold weather and group members may assist each other in the rearing of offspring. In terms of disadvantages, a group may be more conspicuous than an individual, thereby attracting a predator. Once food (or other resource) is found, there is competition for access. Contagious illness is spread more rapidly and effectively through groups.

Within free-living animals, the 'normal' size of the group will depend on the species and the distribution of resources. Groups are likely to be quite dynamic in nature, not necessarily through the active choice of animals leaving or joining a group – though this can occur – but because there will be mortality and birth. Even though a group may have a dynamic nature, there will be mechanisms contributing to maintaining group cohesion. Each animal within the group is usually striving to gain maximum advantage for itself and some will be more

successful than others. Consequently, group members will compete against each other for resource access and, through social interactions, a dominance hierarchy will become apparent. Many of the social interactions involved in hierarchy formation are overtly aggressive, such as attacking and biting, but individuals may appease without being threatened and, once established, the stability of the hierarchy is evidenced from behaviour that is more subtle and less obviously aggressive, such as threats with corresponding withdrawal or retreat, or even by withdrawal or retreat alone.

The precise **ethogram** of agonistic behaviour will be species-specific and, for nearly all species, a full cataloguing and understanding of the behaviours carried out during an agonistic encounter are lacking. Considering the importance placed upon the aggressive components of agonistic interactions and their impact on an individual's welfare, this gap in knowledge is worthy of further study. The major difficulty for ethologists looking in from the outside is to record the behaviours in sufficient detail and also to correctly assign them. Some authors have attempted to describe specific postures, movements and visual signals, etc., but there is still the risk of misidentification or misinterpretation. Major challenges are the speed at which they may be carried out and the fact that observable behaviours may well be accompanied by both olfactory and auditory cues that may act to modify 'meaning'. As stated above, once dominance is established, the subtlety of behaviours needed to maintain social status also makes recording difficult.

Within applied **ethology**, relatively few studies have been carried out to investigate agonistic interactions in detail and to attempt to develop a definitive ethogram of agonistic behaviour. Often, the behavioural category 'agonistic behaviour' may be used in more generalized study of the behaviour of animals being subjected to experimental treatments. Also, most agonistic interactions are very brief, meaning that unless continual direct observation techniques are being used, true quantification of agonistic interaction incidence is unlikely. Scan sampling, in particular, is a poor method for recording the often short-duration behaviours that are performed during agonistic interactions.

A thorough example of an ethogram of agonistic behaviours is that of male horses, described by McDonnell and Haviland (1995). Following a review of the literature, comments from peers and detailed breakdown of 50 hours of video recordings, a final ethogram of 49 behavioural elements, including five distinct **vocalizations**, was described. Three complex behavioural sequences were also described. The individual elements have been assigned names (with a cross-reference to names used to describe the same behaviour in other literature), with a full definition or description of the behaviour given and accompanying comments providing extra information about the behaviour. (JNM-F)

Alarm reaction

The term 'alarm reaction' is used to describe two different behavioural responses. It can refer to the first part of the **general adaptation syndrome**, described by Selye as the general response to a stressor; alternatively, it may refer to a range of behaviours that alert others to perceived danger (warning behaviour), for example following detection of a predator.

During the alarm phase of the general adaptation syndrome, activation of the **sympathetic nervous system** results in the production of **epinephrine** (adrenaline) and **norepinephrine** (noradrenaline) from the adrenal medulla, which helps to prepare the animal for a burst of activity. Physiological changes include an increase in **heart rate** and respiratory rate, an increase in blood sugar (related to a decrease in the production of and reduction in sensitivity to insulin), diversion of blood away from the gastrointestinal system and an increase in flow to the skeletal muscles, together with a reduction in anabolic hormone levels, including a fall in thyroid levels that suppresses the immune and reproductive systems. Many of these changes are used during the assessment of animal **welfare** (see: **Welfare measurement**).

In response to signs of danger, animals may exhibit an alarm reaction that alerts others to the threat. Warning signals may be transmitted through a variety of sensory media and may involve overt and specific signals emitted before taking flight, such as alarm calls, signals associated with the act of taking flight (e.g. the white flashing on the underside of the rabbit tail) and signals that are apparent even after flight has taken place, such as chemical markers (**pheromones**), which may indicate previous danger in an area.

Alarm reactions that alert others may represent a form of **altruism** if they increase the risk to the signaller, but many alarm signals appear to minimize the risk to the individual. For example, alarm calls are often relatively low-frequency sounds with little change in pitch, which are more difficult for a predator to localize. These signals also travel further than high-pitched sounds and may serve to encourage others to emit similar calls or undertake behaviour that might reduce the individual risk further: for example, the simultaneous flight occurring in response to a call might confuse a predator, or individuals might be recruited to attack a predator, increasing the defensive potential of the group. Even if the warning behaviour does increase the risk to the individual it may still be beneficial from an inclusive **fitness** perspective, for example by encouraging related individuals such as offspring to take cover.

Some alarm calls may simply communicate to the predator that they have been detected and so deter **predation**, but others clearly have greater informational value for conspecifics, since in vervet monkeys for example, different types of call may be used in response to different threats. Flight responses

serving as alarm signals include both the appearance of stimuli not normally present, such as the flashing on the white underside of the tail of the rabbit in flight, and the absence of normal stimuli, such as the elimination of intention signals before taking flight, which normally suppress the flight of others in flocks of birds. Allodynia

Allodynia is an exaggerated pain response to normally innocuous stimuli and, although the mechanisms are unknown, allodynia probably arises in the structures of the limbic system of the **brain**, such as the amygdala and periaqueductal grey, which are associated with the processing of emotions. Allodynia may explain some apparently excessive aggressive responses triggered by touch. (DSM)

Allogrooming

Allogrooming (mammals) or allopreening (birds) refers to the care given to the pelage of one individual by another (in contrast to autogrooming, in which an individual grooms itself). Allogrooming serves a hygienic function, given that grooming tends to be directed at sites that are inaccessible during autogrooming and is often directed at offspring that are incapable of autogrooming. However, allogrooming is also important in maintaining social cohesion and **dominance hierarchies**. Among non-human primate societies, allogrooming functions in conflict reconciliation (**see also: appeasement**) and in the building and maintenance of social alliances. It has also been proposed that allogrooming enables individuals to assess their own positions within such societies. Within some primate and non-primate species allogrooming has been associated with **mate choice**, with males increasing their grooming of females around the time of oestrus. For example, in crab-eating macaques a female is more likely to engage in sexual activity with a male that has recently groomed her. (PE)

Alloparenting

Alloparenting describes the giving of parental care to non-descendent kin. This can occur interspecifically, as in the case of a cuckoo chick being fed by its host parents (interspecific brood parasitism) or, more commonly, intraspecifically when conspecifics give care to the offspring of others. In species that practice cooperative breeding, alloparenting is often directed at the young of close relatives, so that the alloparent enhances its inclusive **fitness** through the production of non-descendent kin. However, not all cooperative breeding systems are characterized by **kin selection** and, in these cases, the alloparent is thought to benefit directly through having increased chances of future reproduction via a host of mechanisms including territory inheritance, mate inheritance and coalition formation.

Alloparenting may also arise when parents are tricked into caring for non-kin. In some species of birds, females are known to lay eggs in the nests of conspecifics (intraspecific brood parasitism), while in others females are known to engage in extra-pair copulations that result in extra-pair young that are fed by the genetically unrelated father. (PE)

Allostasis

Allostasis refers to a model of physiological regulation that produces stability through change. It differs importantly from the concept of **homeostasis**, which is a system that focuses on the response to change aimed at returning the animal to a set point, by integrating predictive systems that bring about reactions in anticipation of change. For example, a rise in cortisol (**see: Corticosteroids**) from a homeostatic perspective is seen as a response to stress that helps the animal to cope, whereas from an allostatic perspective it is a reaction in anticipation of further stress that minimizes the impact of the anticipated change in circumstances. From an allostatic perspective it is not the level of cortisol that is so important as a measure of stress, but rather the functioning of the system. Thus, a failure of an appropriate rise may be just as important as an extreme response.

Within an allostatic context the systems are dynamic and may maintain a degree of baseline activity reflecting minimal phylogenetic levels of anticipated challenge; therefore, if an animal is kept in circumstances where that minimal level of challenge is not encountered, then the system may actually be harmful (e.g. in the absence of normal levels of immunological challenge, autoimmune problems may develop). Another feature of allostatic models is the potential importance of previous experience in shaping the response to given challenges. It has been suggested that allostatic models may be useful in evaluating **welfare**, since they explain why understimulation may be as significant a welfare problem as overstimulation. By contrast, a model of welfare based on homeostasis tends to predict that understimulation will maintain homeostasis and therefore minimize **stress**. (DSM)

Altricial

Developmental maturity is recognized as varying between **reptiles**, birds and mammals, with neonatal animals differing in their ability to survive without parental supervision. Neonatal reptiles, and some birds (e.g. the Megapodidae and kiwis), are fully independent of parental care and exhibit 'super-precocial' maturity. **Precocial** offspring are fully mobile but dependent on their parents for food (as is the case in mammals), thermoregulation or protection from predators (as is often the case in birds). Semi-precocial neonates are active and well covered with down or fur, but require feeding by their parents because usually they are incapable of securing their food. Semi-altricial neonates may be well covered with down or fur but are inactive, blind and require brooding and feeding. At the opposite extreme of this spectrum of developmental maturity are altricial neonates of birds and mammals, which are naked, often blind and totally dependent on their

parents for maintenance of bodily functions. These neonates are incapable of effective thermoregulation or movement and require brooding and feeding for an extended period of time after hatching or birth.

Altricial development is often associated with relatively short periods of incubation or gestation. Adoption of this strategy represents a shift from **parental investment** in an extended period of the reproductive cycle that is required to produce precocial offspring to a strategy where the adult is able to provision its free-living offspring more effectively. In birds, eggs producing altricial neonates have a lower energy content and a higher water content, and have a relatively shorter incubation period than those producing precocial offspring. The energy-poor eggs minimize female investment and the short incubation period minimizes predation risk during incubation. Most of the reproductive effort is shifted to the post-hatching period, when the altricial offspring have to be maintained within a nest until they are able to develop bodily functions akin to independent life. (DCD)

Altruism

In its everyday sense, the word altruism refers to the conferring of some benefit on another person at some cost to oneself. It is not usually applied within a family, for it seems obvious that actions such as feeding or protecting one's children are beneficial to one's own interests. Biologists have put this idea more formally, following two very influential papers by William Hamilton, who put forward what has come to be known as Hamilton's rule (Hamilton, 1964). This states that, for altruism to pay, the following must hold true:

$$\text{Benefits to recipient} > 1/r \text{ Costs to donor}$$

where r is the coefficient of relatedness between the two individuals involved, the probability that the two share a gene by common descent. For identical twins this is 1.0 and for siblings it is 0.5, as it is also for parents and offspring; for first cousins it is 0.125. Thus, in genetic terms, it pays to give aid to a full sib if the benefit to them is more than twice the cost to oneself. At an extreme, it may be worth saving a very distant relative from drowning if the risk to oneself is very slight.

Hamilton's rule helps to explain why relatives may help each other, but one could dispute whether this is altruism at all, for the basis of it is that the individual is furthering the interest of their own genes. Is that then all there is to it? While it is certainly true that many examples of apparent altruism are in groups of closely related animals, and may therefore be explained by kinship, there are reasons why animals might also behave altruistically towards non-relatives.

Robert Trivers (1971) put forward the theory of reciprocal altruism. In this he suggested that it might pay an individual to help another if there was a good chance the favour would be returned in due course. For such an arrangement to evolve it was necessary that animals should live in fairly stable groups so that the same individuals would meet repeatedly. It was also important that they would be able to recognize each other, both so that they could form reciprocal relationships and so that 'cheats' (individuals that accepted favours without returning them) could be ostracized. Given these conditions, Trivers argued that altruism might arise in groups of animals.

Reciprocation is obviously a rather important phenomenon among humans: if someone invites us out we tend to invite them in turn. But is there evidence for this among animals? There is, but so far it is quite limited; the theory is rather far ahead of the data. Animals often show cooperation so that two or more individuals derive immediate benefits from their relationship, but this does not involve altruism. For altruism one requires evidence that unrelated animals may help one another without any immediate gain.

The most oft-quoted case of reciprocal altruism is the food sharing of vampire bats (*Desmodus rotundus*). These animals fly out from their roosts at night in search of blood meals. Some fail to find food and might starve if this occurred repeatedly. On the other hand some return to the roost gorged, having found a good source of blood. Under these circumstances animals will share blood with one another even if unrelated and individuals that received blood on one occasion will tend to reciprocate on another. To date this remains the best example of reciprocal altruism among animals in the wild. Another that may be best viewed in this way, and certainly does not involve kinship as different species are concerned, is the relationship between cleaner fish and the larger fish that are their clients. Some of these larger fish are carnivores and could easily consume the cleaner; the cleaners could also go beyond their normal scavenging for parasites and take valuable scales or mucus from the host. But both of them forgo these short-term gains in favour of their long-term relationship.

Other cases may be more properly viewed as **mutualism**, both individuals gaining from cooperating without the need for reciprocation. Pairs of male yellow baboons (*Papio cynocephalus*) may cooperate, one to distract the dominant male in their group while the other mates with his female. This was originally described as reciprocal altruism, but the evidence for reciprocation is weak; instead, it seems most likely that the two combine because both gain a chance of mating and this would be absent were they not to cooperate.

Bird alarm calls have also been suggested as altruistic; an individual sees a predator calling and so warns the others in its group, which will reciprocate when they are the first to spot the hawk. Thus the costs are spread out and all gain in the long term. But it is hard to see how cheating could be avoided in this case, for it would involve the difficult task of identifying an individual that saw a hawk and failed to call. Many more plausible theories of alarm calling, including advantage to kin, have been put forward.

Most cases where animals behave altruistically towards one another may be explained because they are kin, and the altruist gains genetic benefits from the action. In other cases the altruism may be more apparent than real and both individuals may gain, either in the short term or, in the small number of cases that have been described, through later reciprocation. Genuine altruism, where an animal selflessly bears costs for the benefit of another with no possibility of payback, seems unlikely to occur and has not so far been described in animals.

Ambivalent behaviour

Ambivalent behaviour is a form of **conflict behaviour** in which the condition of contradictory motivational states results in behaviour that either oscillates between the motivational states or takes an intermediate form.

An animal is said to be in a motivational conflict when two motivational tendencies are at a similar and high level. For example, a conflict between hunger and fear can arise in the situation where an animal reaches a preferred feeding location and notices the threatening presence of a predator. When the animal is very hungry and does not want to flee, an approach-avoidance conflict occurs. This approach-avoidance conflict could be expressed by the animal rapidly and repeatedly switching between feeding and retreating. In the scenario that the animal is too frightened to feed but at the same time too hungry to avoid the predator the conflict remains unresolved, and this is likely to result in a state of **frustration** in the animal.

A three-way motivational conflict between sexual interest, defence and offence takes place in many species during courtship. An example of such a conflict is the courtship of the cockerel. 'Circling' behaviour is part of this courtship, and during this circling (signalling sexual interest) the wing facing the female is held low (signalling defensive fear) while the other wing is held high (signalling offence). (PHZ)

Amphibian

Amphibians (Class Amphibia) are a major and diverse group of tetrapods that represent the living relatives of the first vertebrates to venture on to land around the Late Devonian (~360 million YBP). Amphibians were dominant during the Cambrian and Permian epochs (354–248 million YBP), until the evolution of reptiles. Modern amphibian forms arose in the Triassic and Jurassic and so have persisted for at least 144 million years.

Today, amphibians are divided into three main groups: caecilians (Order Gymnophiona), newts and salamanders (Order Caudata) and frogs and toads (Order Anura). There are around 5400 species, dominated by diverse species of frogs and toads (~4700 species); newts and salamanders are much less diverse (~470 species). There are fewer than 200 species of the eel-like caecilians.

Characterized by a moist, glandular skin, amphibians are found on all continents with the exception of the polar regions. No amphibians have adapted to life in seawater. At high latitudes cold temperatures drive amphibians to seek refuges on land or water to overwinter in a state of torpor. Some species are tolerant to freezing. Locomotion on land is through walking or hopping, but in water undulations of the body are used by newts and salamanders to swim. By contrast, anurans have shortened vertebrae and elongated legs that combine to

produce a hopping action on land, and swimming is by simultaneous thrusts of the legs. Communication is via visual, aural and chemical means.

A key feature of amphibians lies in their pattern of reproduction. Despite living in terrestrial environments for much of their juvenile and adult life, most amphibians are tied to water for embryonic development. There is a clear distinction in reproductive strategy between caudates and anurans. Newts and salamanders often exhibit elaborate **courtship** and **display behaviour**, leading up to production of a spermatophore by the male that is then taken up by the female into her reproductive tract, which allows internal fertilization. Typically, females of this group then produce relatively few eggs (100–200 per season), laid individually and deliberately hidden. Egg laying often takes place over several weeks. By contrast, frogs and toads tend to return to water *en masse* and sperm is released into the water when the thousands of eggs are released. Egg laying by an individual occurs only once. The adults then leave the breeding pond to resume their terrestrial habits.

Embryonic development proceeds via aquatic larval stages and, again, newts and frogs differ. The larval newt is very similar to the adult in appearance for much of its time in the water. Frog tadpoles are quite different from the adult for much of the aquatic stage: for instance, they possess a tail. Development proceeds to a final metamorphosis, producing an air-breathing juvenile that will typically leave the breeding pond for a terrestrial habitat. Amphibians are carnivores in their adult forms although in many species the larval species are herbivorous or omnivorous.

In some salamanders the final stage of metamorphosis is never completed – often through a lack of iodine in the environment, which is essential for the formation of thyroxine, a key hormone controlling metamorphosis (see: **Thyroid hormone**). In these cases the juvenile continues to grow in the water and becomes sexually mature and active. Such neoteny development is most typically associated with the axolotl (*Ambystoma mexicanum*).

Amphibians are found in captivity as pets, for commercial production and as subjects for scientific research. The numbers of species kept under such circumstances are relatively few but pet frogs, toads and salamanders, particularly the axolotl, are popular and becoming increasingly so. Commercial exploitation of amphibians often lies with their production of meat, which in some parts of the world can be very significant. Research is directed at a few species, such as the common frog (*Rana temporaria*) or the clawed toad (*Xenopus laevis*), which are kept in laboratory conditions. Amphibians of all types are the subject of research in their natural habitats all around the world.

One species, the cane toad (*Bufo marinus*), which was introduced to some regions (such as Australia) as a biological agricultural pest control measure, has been very successful biologically (though less so as a pest control measure) and has caused considerable ecological damage as it is highly toxic to native predators (see: **Exotic species invasion**). However, there occurred a worldwide decline in amphibian numbers and diversity during the 20th century, which appears to be accelerating in the 21st century. There are a variety of factors causing this decline, including pollution, exposure to excessive

amounts of UV light, habitat loss, introduction of non-native predators and competitors, and commercial exploitation. One key problem is the spread of the parasitic chytrid fungus on a global scale that is threatening many species with extinction in the wild. These problems mean that amphibians are increasingly being brought into captivity as a conservation measure.

Welfare issues with amphibians lie primarily with the poor understanding of their specialized needs in captivity. Handling should be minimized to prevent damage to the skin, but also to prevent excessive rises in temperature in the smaller species. The correct environment and housing need to be provided to ensure that the appropriate temperature and humidity conditions are maintained. Appropriate nutrition and health care are also causes for concern with captive amphibians. (DCD)

Anaesthesia

A state of not being able to feel; often applied to a whole animal being 'anaesthetized' (general anaesthesia – GA), but can also apply to a part of the body (local anaesthesia – LA). GA can be induced by means of a liquid chemical substance (or mixture of chemicals) that is injected into an animal, or the chemical may be vaporized and inhaled (e.g. ether, isoflurane); occasionally it may be given orally. GAs work by depressing the **central nervous system**, but sometimes a mixture of chemicals is used to provide the three major aspects of GA, i.e. **restraint**, **analgesia** and muscle relaxation (so-called balanced anaesthesia). Balanced anaesthesia is normally safer than general anaesthesia, as none of the individual chemicals used approaches its toxic level.

Local anaesthetics work, on the other hand, by blocking nerve conduction to produce a numbness in a particular area of the body by either: (i) local infiltration affecting only the nerves in that area; (ii) blocking the nerve that supplies that region (nerve block) at a site away from the area of interest; or (iii) injection into the vertebral column affecting the spinal cord, from which the nerves that supply that region originate.

Anaesthesia can be induced in some species by immersion when chemicals are absorbed through the skin (e.g. amphibians) or via the gills (fish).

During anaesthesia the autonomic controls and reflexes – for example, to low oxygen and low body temperature – are reduced or removed and so it is important to monitor physiological states and maintain **homeostasis** artificially through monitoring of blood gases and body temperature and compensating when necessary.

The behavioural effects of anaesthesia on animals vary according to the species but, in general, as an animal becomes anaesthetized it loses control of its motor functions such as its righting reflex, and it will fall about uncontrollably. As it becomes deeper so it will lose various protective responses, e.g.

the blink reflex to touching the cornea of the eye, the withdrawal reflex to a potentially painful pinch to the foot and, at this point, it is normally safe and humane to carry out surgical interventions. As an animal recovers from surgical anaesthesia so these reflexes are regained in the order in which they were lost. If, however, the animal goes deeper, the central depression may progress to one where it loses its respiratory drive, and the lack of oxygen to the heart and **brain** will lead to a loss of respiratory and cardiac functions and, ultimately, **death**.

The behavioural effects of anaesthesia are not just confined to the period of anaesthesia but also affect the animal's **circadian rhythm** for several days afterwards. Depending on the type and duration of anaesthesia, as well as post-anaesthetic care, the heart rate, temperature and mobility can all be affected for 4 days or more. Moreover, some anaesthetics render a second anaesthetic less predictable in terms of duration and depth, particularly those anaesthetics that must be metabolized for recovery, e.g. barbiturates. Those anaesthetics that rely on exhalation for recovery are better tolerated. (DBM)

See also: Analgesia

Analgesia

A state of not being able to experience pain. This is part of **anaesthesia** but it is a state that can also be specifically induced with chemicals, e.g. morphine, and with physical forces, e.g. rubbing or exposure to cold. Ideally, treatment of pain, e.g. after surgery, should be preventative (so-called *pre-emptive analgesia*) rather than after pain has been experienced by the patient, as the feeling of pain can result in a condition known as 'wind-up'. Wind-up sensitizes the spinal cord, resulting in a local spread in the area where pain can be felt, as well as an increased intensity of pain felt at the site (**hyperalgesia**); furthermore, previously non-painful stimuli become painful (**allodynia**).

Stress and heavy physical exertion (e.g. exercise) can induce analgesia by acting centrally to promote the release of natural opioids. Analgesics can work centrally (e.g. opioids like morphine) or peripherally at the site of pain by acting on the inflammatory response to injury (e.g. non-steroidal anti-inflammatory drugs (NSAIDs), affecting prostaglandin metabolism) or by blocking impulse transmission along afferent sensory nerves (local anaesthetics). Paracetamol (Tylenol®) is another centrally acting analgesic, but its mechanism of action is not clear. Centrally acting opiates bind to the mu (μ) agonist, which has the advantage that it lasts for several hours – even up to 8 h in some species (dog and cat).

The behavioural effects of an analgesic will depend on the drug being used. Some drugs stimulate the appetite whereas others may cause respiratory depression to the point of cyanosis (blue coloration of the mucous membranes), although this is far less profound in animals than in humans and so drugs such as the opiates are safer to use. (DBM)

Analogy

Two structures are said to be analogous if they have the same or similar function although their evolutionary pathway is different (this process is known as **convergent evolution**). A

classic example of analogy is the wings of insects and birds: they evolved independently but have a similar function. (BM)

See also: Homology

Androgens

Androgens are a family of **steroid hormones** principally concerned with the development and maintenance of the male sex characteristics and gamete production. The term androgen is also used to encompass other molecules with androgen receptor-binding properties, including steroidal and non-steroidal synthetic compounds able to act as androgen receptor agonists. Androgen molecules have 19 carbon atoms (C-19) arranged in a basic four-carbon (cyclopentanoperhydrophenanthrene) ring structure common to a wide range of steroid hormones. A complex biosynthetic network utilizes cholesterol to first make pregnenolone, which acts as a general precursor for a number of steroid hormones including, among the androgens, relatively low-activity molecules such as dehydroepiandrosterone (DHEA) and androstenedione, which subsequently undergo further processing to make the more active **testosterone** and dihydrotestosterone (DHT).

Although studies on **castration** described from the early 1700s onwards had shown that a testicular factor was responsible for expression of the masculine appearance and behaviour, it was not until 1936 that testosterone was identified and characterized by Leopold Ruzicjka. The primary source of androgens in vertebrates is the testes; however, androgen production is maintained at very low levels in juvenile males and increases significantly only at the time of puberty, when testosterone production is initiated in the interstitial Leydig cells by the action of pituitary **gonadotropins**, particularly **luteinizing hormone** (LH). Post-pubertal testosterone production is regulated by a series of feedback mechanisms operating within the hypothalamic–pituitary–gonadal endocrine axis. Increased circulating androgen levels at puberty initiate spermatogenesis in the testes and are responsible for acquisition of, and thereafter maintenance of, the secondary male sex characteristics and other androgen-dependent structures such as the accessory glands.

Prenatally, androgens also play a crucial role in fetal development. The fetal testes are active in testosterone production from an early stage in development and it is testosterone that signals development of the male internal and external genitalia; in the absence of this androgenic support the default female morphology is expressed. Fetal androgens also play an important role in gender-specific differentiation of the brain, acting during fetal life for the promotion of development and maintenance of sex-specific behaviour. Sexually dimorphic behaviour patterns in postnatal development are also dependent to some degree on circulating levels of gonadal steroids.

Androgens are known to exert profound effects on the organization and function of the **central nervous system**, a range of androgen receptors has been identified in different brain regions and there is increasing evidence in support of the general hypothesis that testosterone levels influence aspects of **cognitive** function. There has been an extensive amount of work investigating the effects of circulating androgen levels on the promotion of **sexual behaviour**, but also considering other types of behaviour patterns and particularly in connection with **aggression**.

In addition to the testes, the cortex of the **adrenal gland** is a secondary source of low-affinity androgens, in both males and females. In the adult male these low-activity forms can be converted to testosterone and DHT in a range of peripheral tissues, but the amount of testosterone produced via this route is probably not physiologically significant, amounting to only around 5% of total circulating androgen levels. However, during fetal development in the prepubertal male and in the female, the adrenal gland may be an important source of androgen. Although androgens have been considered as the definitive male hormone they do have essential physiological roles, including maintenance of muscle and bone and behavioural effects in the female, where production is divided fairly evenly between the ovaries and the adrenal glands. In addition, androgens are vital within the female endocrine system as they provide an essential precursor that undergoes a process of aromatization to produce **oestrogens**, which may be considered as the female counterpart to the male androgens.

Testosterone has been shown to have potent anabolic effects on the musculoskeletal system, including an increase in lean body mass, a dose-related hypertrophy of muscle fibres and an increase in muscle strength; androgens can also inhibit protein catabolism and fat deposition. Synthetic androgen derivatives such as trenbolone, a steroid with a threefold higher affinity for the androgen receptor than testosterone, have been extensively used as growth promoters within the livestock production industry. The effects of supraphysiologic doses of exogenous androgens on muscle mass and strength have led to their continued use and abuse as performance enhancers.

Animal abuse

Animal abuse or **animal cruelty** involves causing significant harm to animals, when a person either intentionally and actively harms an animal or fails to act appropriately towards an animal for which he/she is responsible. In most legal texts, harm to animals is not considered cruelty or abuse if it takes place within accepted agricultural, management or research practice and if the harm is not greater than considered necessary to obtain the purpose.

(AO)

Animal activist

An animal activist is a person who engages in different actions to bring about changes to the treatment and/or status of animals. This activism can include a wide variety of actions and positions, but people referred to (by themselves or others) as animal activists tend to hold more radical positions.

Animal-assisted therapy

In recent years, increasing attention has been paid to the potential therapeutic benefits that interactions with animals can have in the lives of ill, disabled and disadvantaged individuals. The expression ‘animal-assisted therapy’ has been coined to refer to a variety of treatment programmes that employ animals, usually in association with a handler, in formalized therapeutic interventions with patients or clients. Related expressions include ‘pet-facilitated therapy’ and ‘animal-facilitated therapy’. Hospital visitation schemes are a

common form of animal-assisted therapy programme. These involve a **companion animal** (usually a dog) and its handler visiting hospital patients, particularly children, elderly and psychiatric patients, on a regular basis.

Similar schemes are also employed to bring nursing home residents into contact with animals. The aim of such schemes is to provide interest, entertainment and distraction from pain, distress, anxiety or depression, and to offer patients opportunities for interaction and conversation (e.g. see Bernstein *et al.*, 2000; Marr *et al.*, 2000). Such programmes are thought to have therapeutic effects via a number of different routes. For example, the opportunity for tactile contact with another living being may confer feelings of relaxation and well-being to some patients; for others, animals may serve as a facilitator, enabling interaction with the handler and other patients. The unconditional affection that many animals offer also provides additional support to those for whom disability, deformity or infirmity limits successful interactions with other people. Such schemes are not a modern invention: as long ago as the 18th century, a York retreat in England included animals within its environs. Interest in such therapeutic interventions, however, has grown substantially in recent years, with several umbrella organizations supporting such work emerging in a number of countries across the world.

Animal-assisted therapies among prisoner populations take a wide variety of forms. Some are similar to hospital visitation programmes, with volunteer handlers and dogs coming into prisons to visit particular inmates within the system. Others are on-site programmes, in which prisoners care for and raise livestock, train dogs or horses, rehabilitate wildlife, socialize guide dogs, etc. At a less formal level, many prisons also now allow inmates to keep and care for companion animals individually, in the hope that such experience may help to instil compassion and empathy, as well as practical caregiving skills. Such programmes, however, can give rise to concerns about the welfare of the animals involved. Educational interventions, and supervision of training and caregiving activities, can help to ameliorate such risks.

Therapeutic horse-riding and -driving programmes aim to benefit disabled children and adults physically, emotionally and cognitively. Often, over a period of many years, riders and drivers are taught horsemanship skills, helped to develop balance and strength and may also experience boosts in self-confidence, social skills, the ability to communicate with others and follow directions given by the instructor. Organizations dedicated to equestrian-based therapy (hippotherapy) programmes include the Riding for the Disabled Associations of the UK, Ireland, New Zealand and Australia, the North American Riding for the Handicapped Association and the French Association Nationale Handi-Cheval.

Therapies involving wild animals such as dolphins have increased dramatically in popularity in recent years. However, such schemes are usually considerably more expensive to operate than volunteer-based visitation programmes, given the extensive overhead costs of accommodation, feeding, husbandry and training of the animals concerned. Waiting lists are common, and therapeutic contact is frequently limited to just one or two relatively brief sessions. Despite this, such programmes attract high levels of public support, with the potential benefits that interactions with dolphins may confer

on children with autistic spectrum disorders generating considerable popular attention (Smith, 1988).

Despite the increasing popularity of animal-assisted therapies, there has been relatively little empirical research into the efficacy of such programmes. In many of the studies that have been conducted, problems have arisen with respect to small sample sizes, lack of adequate control groups and outcome assessments being made by observers who are not blind to the treatments assigned. In addition to such methodological problems, the nature of any potential benefits of animal-assisted therapy is likely to be multifaceted, often subtle, and frequently difficult to measure in an objective fashion. Effects are also likely to vary considerably from one user to another, depending on their previous experience with and attitudes towards the animal species concerned. Regardless of these problems, however, those providing animal-assisted therapy are clearly encouraged by the simple enjoyment that many people derive from the contact they experience with animals. In addition, the interest that such schemes generate in patients and staff alike, and the sometimes dramatic improvements that appear to be associated with the initiation of treatment in some individuals, encourage many to believe that animal-assisted therapy often provides a beneficial experience.

On the negative side, animal-assisted therapy programmes also present potential health risks to patients and clients, particularly in the form of infection and injury. The majority of programmes therefore employ strict guidelines regarding animal selection, cleanliness and safety precautions in order to minimize such hazards. Another potentially negative issue within animal-assisted therapy concerns the welfare of the therapeutic animals used. With domestic species such as dogs, selection procedures can help to alleviate this by excluding animals that are temperamentally unsuited to the task at hand (e.g. those that show anxiety in the presence of unfamiliar adults or children). With wild animals such as dolphins, additional and more rigorous safeguards, including appropriate amounts of 'time out' from therapeutic sessions, need to be built into programmes.

Animal-assisted therapies are distinct from the use of assistance or **service animals** (such as guide dogs for the blind and hearing dogs for the deaf), in that their primary purpose is therapeutic rather than practical. Nevertheless, there are many overlaps between the uses of therapeutic and assistance animals. For example, many prison-based animal therapy programmes involve the training of dogs to be used as assistance animals for the disabled. In these instances, the organizations are specifically structured so that the same dogs are acting as both therapeutic and assistance animals (for the trainers and end-users, respectively). At a more informal level, guide dog owners frequently report social and emotional benefits, as well as more specific practical benefits, arising from the relationships they form with their dogs. (EP)

Animal cruelty

Cruelty to, or abuse of, animals involves causing these animals significant harm. A person who acts cruelly to an animal can either intentionally and actively harm the animal or fail to act appropriately in relation to an animal for which he/she is responsible. This failure to act usually involves neglecting to provide the animal with wholesome food, water, appropriate shelter or necessary veterinary care.

Legal protection of animals against cruelty dates back to at least the 18th century BC, with some elements in the Codex Hammurabi of ancient Babylon and the Atharva Veda of Hinduism. The first Western law against cruelty to animals was contained in the Massachusetts Bay Colony Body of Liberties in 1641; however, it did not remain part of the laws of the colony or the later state of Massachusetts. The first enduring parliamentary animal protection law was established in the UK in 1822, when what was later to be termed The Martin's Act (after its promoter Richard Martin) made it a crime to wantonly and cruelly beat or ill-treat any 'horse, mare, gelding, mule, ass, ox, cow, heifer, steer, sheep or other cattle'. This law was followed by similar legislative texts in other northern European countries and North American states during the following decades, including the New York State anti-cruelty law (1828 for cattle, amended in 1866 to include all animals), the Saxonian criminal law (1838) and the French *Loi Grammont* (1850). Parallel to the establishment of legislation in the 19th century, and instigated by the same public debate, the various associations for the prevention of cruelty to animals were developed. The best known of these associations is probably the British **Royal Society for the Prevention of Cruelty to Animals**, established in 1824.

Under earlier legislation, mistreatment of animals was considered illegal only to the extent that it harmed the owner of the animals by harming his property. However, even though The Martin's Act extended the legal protection for animals, it covered only cruel acts towards an animal when committed by those persons other than the animal's legal owner. The protection was further limited by the fact that this Act, as well as most other legislation against animal cruelty in the 19th and early 20th centuries, only considered instances where animals were subject to deliberate and unjustified harm. What determined whether an act was cruel was not the harm as such, but the context in which it was inflicted and whether there was any objective purpose behind the action.

During the second half of the 20th century, animal protection legislation was developed not only to ban abnormal practice (wanton cruelty) but also to regulate normal practice, in particular in farm animal production, **transport** and **slaughter** and in animal research. In many countries, there is now specific legislation laying down the conditions for the housing, handling and husbandry of these animals; however, enforcement varies enormously between countries, and sometimes within countries. Such legislation aims to protect the **welfare** of the animals involved and may, for example, demand that **analgesia** is always used in painful procedures,

that animals are guaranteed basic levels of comfort and freedom of movement and may even prohibit certain specific practices (such as the tethering or crating of pregnant sows, already prohibited in several European countries and regulated through a European Directive affecting all member states by 2013). Whether or not harm within regulated practices in animal production and research is ethically justifiable, however, remains a matter of debate. In many cases, animal protection and **animal rights** associations refer to harm done to animals also within such circumstances as cruelty or abuse.

In Europe, legal animal protection is increasingly regulated at the European Community (EC) level. The first transnational regulations were the Council of Europe Conventions covering international transport of animals (ETS 65 from 1968), farm animals (ETS 87 from 1976), slaughter (ETS 102 from 1979), laboratory animals (ETS 123 from 1986) and companion animals (ETS 125 from 1987). In most cases, a convention has later been followed by a legally binding European directive. From the EC, there has also been an effort to bring animal welfare into international trade agreements. The OIE (World Organisation for Animal Health) has identified animal **welfare** as a priority, with guiding principles laid out in the Terrestrial Animal Health Code 2004. Welfare standards have now been produced for animals during transport and slaughter.

Altogether, the process of expanding legislation reflects an increasing concern over the welfare of animals – but essentially a concern that does not question the use of animals as a principle. A more demanding view on legislation has been increasingly defended during the last two decades by some **animal activists**, including philosophers and lawyers, who claim that animals deserve respect as such and that they have a right to life, and that legislation should grant them such rights. One example is the Great Ape Project (<http://www.greatapeproject.org>), which aims 'to include the non-human great apes within the community of equals by granting them the basic moral and legal protection that only human beings currently enjoy', and consequently strongly restricts the situations when these animals could be harmed. Animal enclosure

Animals have been kept by man for a variety of reasons including religion, food, entertainment and as symbols of wealth and power. The earliest date of an animal housed in a zoo-type situation comes in the form of an illustration going as far back as 2495 BC.

In more modern times cages are normally associated with animals in zoos, research laboratories or battery farms. Cages exist in all shapes and sizes, from those designed to hold insects to those constructed to house large mammal species such as lion. When considering the type of environment in

which an animal is going to be held, it is important to have some idea of its natural behaviour. Provision within the cage of an opportunity to explore and deal with challenges may be essential, if the creature is to be prevented from becoming bored and apathetic or frustrated (see: **Boredom; Frustration**). It has been shown that rats kept in an unstimulating environment, even when given complex motor tasks to perform, have smaller brains than those individuals living in enriched, complex cages. Cage **enrichment** should not be thought of as the exclusive preserve of complex mammal species. Research carried out on the behaviour of spiders has shown that they are also affected by the complexity of the environment in which they are caged.

It is generally perceived that the larger the cage the better. However, it was Heini Hediger who suggested that it was not the quantity of space that an animal was provided with that matters, but the quality. Hediger's suggestion was that a small but high-quality environment was better for the animal than merely providing it with space that either it may not feel secure in or was an inappropriate situation for its behavioural repertoire to be expressed. Hediger also discussed the human concept of what a caged animal was lacking in its life, when compared with the freedom of its wild counterpart.

An animal in the wild has a territory of a certain size, as this area provides it with the resources it requires. The wild animal does not wander without restrictions for the simple sake of expressing its freedom to travel. Primarily it travels to protect its territorial resources, namely food, water and a mate.

Cages have been constructed from a wide combination and variety of materials. Regardless of the materials used, an animal cage should be designed to fit the specific needs of the intended occupant. It should keep the inhabitant secure, have places for hiding and, if outdoors, should provide shelter from the elements; and, in the case of zoos, it should not be open to viewing by the public on all sides. An animal cage should be designed, where necessary, to afford protection to the occupant from any predators that may exist in the external area.

Depending on the species involved it may be essential to equip the cage with different gauges of perching, so that the animal, bird or insect can utilize the maximum height of the area involved. Using shelves, branches and ledges around a cage increases the usable surface area. Certain species like to rest above the ground, and safely secured, suitably sized supports should be provided for this purpose. Some species (e.g. marmosets) benefit from the perches in their cages being able to move, as the branches of a tree would in the wild, while others – specifically bird species – benefit from the perches being a specific diameter. The floor and walls of a cage, depending on the species involved and the purpose for which it is being kept, can be utilized to maximize the cage's potential. In the case of large zoo cages, the animal involved may benefit from some of the enclosure walls being clad in rough timber planking, which can be clawed or rubbed against. Wood in general is a preferable surface for animals to make comfortable contact with than the metal bars or brick walls that may make up the cage structure. However, for some species the bars of a cage can offer a worthwhile, useful surface for climbing on.

The **floor** of any cage is extremely important and should reflect the needs of the animal and the purpose for which it is

being held. For instance, the laboratory animal may need to be kept in a sterile environment, whereas the zoo or farm animal may not be subjected to such strictures. Substrates can be used to cover the floor and make it more user-friendly for the creature involved. Substrates add a whole new dimension to a cage and have many different benefits. For some species soft substrates can be kinder to the feet and legs, allow for play behaviour and digging and provide a surface where food can be hidden to encourage foraging. Appropriate substrates have also been shown to be self-sterilizing, allowing helpful bacteria to grow to the detriment of others. Deep woodchip flooring has also been associated with a reduction in parasite levels in captive carnivores.

A number of countries have opted for a mandatory code of practice that dictates minimum cage sizes for captive animals in zoos, laboratories and farms. But many have an ad hoc system where some categories of animals are covered while others are not. Standardized legislation is, however, proposed for all laboratory and zoo animals within the European Community (EC) countries.

Laboratory rodent cages are predominantly manufactured from polycarbonate, formed into boxes and fitted with a stainless steel lid. For convenience these cages are usually slid into a mobile rack that holds a large number of cages. The cage base and lid are made from high-quality materials that can withstand the rigours of being autoclaved and sterilized. The lid may be fitted with one or two wire food hoppers and space to accommodate a water bottle. Many different styles of **laboratory animal** caging are available for housing. A small selection is highlighted here to give a general feel for how many animals are allowed to be housed in each style mentioned, in compliance with the Home Office Animals Scientific Procedures Act 1986, currently in place in the UK, by way of example of what are generally considered to be high standards for animals in this environment.

Three styles of standard mouse cages are commonly used in laboratories. One of the smallest, referred to as a short box by the care staff, can hold up to three adult mice. They measure approximately $33 \times 15 \times 13$ cm (internal size $330 \text{ cm}^2 \times 12$ cm). The second standard mouse box is generally referred to as a long box, measuring approximately $48 \times 15 \times 13$ cm (internal size $490 \text{ cm}^2 \times 12$ cm), and is deemed suitable for the accommodation of up to four adult mice. The third type of standard cage is considerably larger, measuring $45 \times 28 \times 13$ cm (internal size $960 \text{ cm}^2 \times 12$ cm). This type of cage can be used to house nine adult mice.

As one would expect for laboratory rats, the space requirements are greater (see Table A.1). One cage type in vogue comprises a base of moulded polypropylene with a high wire lid fitted on top to give the animals extra height. This cage measures $56 \times 38 \times 25$ cm (internal size $1575 \text{ cm}^2 \times 25$ cm),

Table A.1. Housing space allowances for laboratory mice, rats and rabbits in the UK.

Species	Typical weight (g)	Floor space (cm ²)		Height (cm)
		Single	Group	
Mouse	> 30	200	100	12 (min)
Rat	350–450		300	20
Rabbit	4000–6000		3300	45

and can be used to house five rats of the weight listed in the table.

Rabbits, in many establishments, are now held in floor pens rather than in individual cages. Home Office legislation in the UK also requires that animals are provided with appropriate cage **enrichment**, and this usually comprises bedding materials, cardboard fun tunnels and chewing blocks, depending on the species concerned.

Laboratory cats are usually kept in large rooms. Cats can be held in small social groups of up to 12. Various forms of caging are used but, regardless of the style, minimum floor space and shelving must be provided. Proposed UK legislation dictates that one cat in a room should have 1.5 m² of floor space, 0.5 m² of shelving and the cage height must not be less than 2.0 m. For each additional cat added to the room, 0.75 m² of floor must be provided and 0.25 m² of shelving. For cats litter trays (300 × 400 mm) should be provided at a rate of one for every two cats. Toys and food puzzles should also be provided, and trays of grass for them to chew are recommended.

Additional legislation is in place to cover the accommodation in cages for breeding groups of laboratory animals, and it is essential to check with the appropriate authorities for up-to-date information.

Until the 1950s most chickens kept for egg laying were kept in a free-range situation during the day and locked up for security at night in a barn or courtyard. From the early 1960s the number of free-range chicken farms in many industrialized countries began to decline in favour of battery systems. Today, the minimum cage sizes used for battery hens are a point of contention in Europe and it is generally acknowledged that the welfare standards for chickens held in such conditions are poor (**see: Laying hen housing**). As the birds do not have much space to move around their bones become brittle and their muscles weak. Several countries have called for a ban on battery caging on the grounds that the birds held in such systems experience acute **welfare** problems. In the European Union (EU) battery cages allow for between 450 and 500 cm² of cage space per bird. It has been estimated that, on average, a resting chicken needs 600 cm² of space. At the moment 90% of the EU's egg-laying hens are housed in battery cages. However, the EU has agreed to ban battery-caging systems by 2012.

For zoo animals, countries such as Switzerland have in place regulations that cover minimum cage sizes for dozens of species. These regulations include an extensive list of the animals' special requirements, such as 'muddy pool – possibility for pigs to wallow and root' and 'screens – possibility to withdraw and hide'. For example, for a group of three gorillas the outdoor enclosure surface area should be 50 m² and the volume of the area should be 200 m³. The indoor enclosure should have a surface of 50 m² and a volume of 200 m³. For a pair of rhinos, the outside enclosure should have a surface area of 500 m² and the indoor enclosure should have a surface area of no less than 25 m² per animal. Regulations for the keeping of a number of marine mammals are supplied. As an interesting example, to keep two killer, white or pilot whales, the surface area of the pool should be 400 m² and have a minimum depth of 4.0 m. The pool volume should be no less than 1600 m³. Special requirements for keeping whale species include an overall circulation rate (of the total water volume) through the filters in a maximum of 4 h, and the pool should

contain salt water. It is also required that an adjoining pool and separating pool be provided, at least one offering the possibility of an independent water supply.

More recently, Petherick and Phillips (2009) have proposed a number of formulae based on allometric equations to calculate space allowances for animals in different contexts, below which there is evidence of adverse effects on welfare. These can be applied cross-species and this approach may be fruitful for deriving recommended minimal size requirements for a wide range of animal enclosures. (GL)

Animal Ethics Committees

Animal Ethics Committees (AECs) are established to protect the **welfare** of animals used in research, teaching and training and, in some countries, they are required by law. AECs operate in a range of organizations, including universities and research institutes, research sponsors, scientific journals, scientific societies and animal trainers. AECs sometimes publish guidelines on how animals should or should not be treated, and what is best practice for the care of the animals and the quality of science, teaching or training. It is the Ethics Committee's duty to ensure that animal use complies with the spirit and intention of any law and guidelines. When seeking ethical approval, animal users must show that the guidelines have been, or will be, adhered to.

When assessing the ethical acceptability of animal use, most AECs adopt a **utilitarian** framework. The principle of this framework is that it is ethically justifiable for animals to be 'used', as long as there are benefits and any costs involved are proportionate to the expected gains. Benefits are considered to be improvements in the quality of life for humans, other animals and the environment; costs can include animal welfare concerns, reduced survivability, a reduced potential for breeding success or damage to the environment. AECs most frequently use a cost–benefit analysis, in which the benefits are balanced against the costs; however, the overall aim is to minimize the costs, not simply to outweigh the benefits. In

science, great costs can be 'offset' in the cost-benefit analysis by achieving a high quality of research and/or answering very important questions, as summarized in Bateson's Ethical Decision Cube (Bateson, 1986). AECs consider that welfare should be assessed at the level of the individual animal, so the numbers of animals used should be minimized without compromising the power and validity of the research. The composition of AECs varies, but they usually include scientists (both expert and non-expert in the subject), veterinarians, statisticians, ethicists, other experts and lay persons (often a theologian). Bateson, P. (1986) When to experiment on animals. *New Scientist* 109, 30–32.

Animal experiments

Research that involves the use of living animals, usually vertebrates but also some invertebrates (e.g. in the UK this applies only to *Octopus vulgaris*), that is carried out with the intention of providing new information in the area of study, is often subject to some form of legal control, e.g. licensing of the person doing the work, as well as of the research programme and the premises.

The procedures used may be invasive, such as transplant surgery, or non-invasive, such as observing normal maternal behaviour. Even if a minor procedure is being used, such as taking a blood sample or plucking a feather, if the procedure has the potential to cause **pain, suffering, distress** or lasting harm, the work may have to be covered by the relevant licences. Some areas may involve wildlife research as opposed to animals in a laboratory and this can also be invasive, through the use of, e.g. location devices or those that monitor internal physiological performance (heart rate, blood pressure, etc.) or position (fish depth in the sea, the position of migrating birds by satellite tracking, etc.). The number of procedures carried out on an animal as part of a research protocol will vary according to the particular experiment.

Animals are often used as models in experiments, and the main aims of these 'animal experiments' are generally to:

1. Acquire new knowledge that may prove useful in the treatment or understanding of normal functioning or disease in humans and other animals.
2. Elucidate any toxicity that a chemical may cause, as well as to determine the target organ and the dosage level at which it does this (safety tests) according to how it is to be used (different hazards can arise depending on a chemical mode of action and method of administration, e.g. a chemical released into the environment in a spray may affect wildlife as well as human operators; a medical treatment for a person may have side effects and the margin of safety is that area between its therapeutic and its adverse effects).
3. Ensure the safety of medical and biological products such as vaccines and saline drips.

4. Make a diagnosis using animals in bioassays, e.g. for shellfish toxins, to protect the environment or to provide information on an endangered species.

The level of animal suffering during an experiment will be influenced by the species, housing and husbandry of the animals, as they are often kept in cages or pens for all of their lives, in addition to the effects of the scientific procedures. More often than not, any animal suffering is not caused deliberately but is an unwanted side effect (consider transplant research where the objective is to test a new immunosuppressant drug in a model of kidney transplantation – the surgical model will produce some pain, but the aim of the experiment is to develop better anti-rejection drugs). On some occasions, the research may be into a particular type of suffering, e.g. pain. In this sort of work the aim particularly has to be to cause only the minimum degree of pain to achieve the scientific objective, although this should be the aim in all areas of research.

In some countries the level of pain involved in an experiment is limited to a notional level (mild, moderate and substantial are permitted categories in the UK, and any level of suffering has to be justified) according to the perceived worth of the research project. Compare research into a life-threatening disease in humans like AIDS with wildlife research. In the former a higher level of pain may be permitted than in the latter.

Since 1990 there has been a dramatic increase in the creation and use of **transgenic** animals, notably mice, replacing the more traditional use of animals. Transgenic animals may suffer depending on the exact nature of the genetic modification, and it may range from none at all to substantial; in some cases there may even be a welfare benefit. In most developed countries animal research is carefully controlled through laws that aim: (i) to replace living animals altogether (e.g. cell cultures); (ii) to reduce the number of animals used to the minimum; and (iii) not to cause more suffering than is necessary to achieve the scientific objective (**see: Three Rs principle**). There are several ways in which legal controls are implemented, either through a national competent authority, a local ethics committee or a mixture of both. In the UK it is through a national licensing system under the Animals (Scientific Procedures) Act 1986 that is administered by the Home Office, coupled with a local process of ethical review; similar frameworks exist in many other countries. In the UK, there are three types of licence: (i) the research premises are approved as being suitable for the research and are inspected by the Home Office in order to be registered and granted a *Certificate of Designation* as either a Breeding, a Supplying or a Scientific Procedure establishment; (ii) the programme of research is approved through a *Project Licence*; and (iii) the person carrying out the procedures on the animals is granted a *Personal Licence* in order to gain competence through training and supervision. All three types of licence aim to produce good scientific data with the minimum of animal suffering.

The number of animals used in research varies depending on the country, but in the UK it was about 3.2 million in 2007, whereas it is estimated to be around 80 million in the USA (they do not routinely count all the animal species used, unlike in the EU). Of these, 83% involved mice, rats and other

rodents, 10% were fish and 4 % birds. Four thousand primates were used; of this number in the UK, 21% were used for the research and development of human medicines, 5% for veterinary medicines, 31% for fundamental research and 13% for safety testing. About 36% of the total animals used were genetically modified (93% mice, 6% fish). (DBM)

Animal Health and Welfare Officer

This is a person who is identified in the **Animals (Scientific Procedures) Act 1986** as the Named Person in Day-to-Day Charge (unofficially renamed as the Named Animal Care and Welfare Officer (NACWO)). His or her role is to ensure the day-to-day care of all animals in the research establishment that is part of an institute's animal research programme. S/he has certain responsibilities, including drawing the attention of scientists licensed to carry out research to any experimental animal whose welfare gives rise to concern, and to deal with any other animal that is not the responsibility of a licensed person, e.g. a stock animal that may need care. Animals that give rise to concern include those that may have exceeded the permitted level of severity that has been designated in the project licence protocol. The NACWO may report directly to the Home Office Inspector, if necessary. (DBM)

Animal hoarding

Animal hoarding describes the collection of animals (of one or more species) by an individual to the extent that it exceeds their capacity to care for the animals to an acceptable level; this lack of care is not usually acknowledged or recognized by the individual concerned, leading to the suggestion that this condition may reflect a mental health disorder. Animals are usually kept in unsanitary conditions and are often undernourished, with a significant proportion requiring veterinary attention. The situation not only results in severely compromised welfare for the animals, but often a serious public health problem as well. There have been few scientific studies into animal hoarding, although it is recognized as occurring by relevant agencies (e.g. local government authorities and larger **animal rescue** organizations) in the industrialized world. Scientific literature suggests that hoarding of cats may be more common than of dogs, both of which are markedly more common than the hoarding of other species. (DSM)

Animal integrity

Rapid and radical modifications of animals brought about by conventional breeding and (especially) advanced biotechnologies sometimes raise public concerns. **Bioethicists** have coined the phrase 'animal integrity' to express one such

concern. The basic idea is that we should not violate the integrity of animal species. 'Integrity' here means *wholeness* or *intactness*.

This idea seems to assume that animals have a relatively fixed nature and that human interference with this is morally (or perhaps aesthetically – it is sometimes hard to tell what is at stake) objectionable. There are several difficulties with this attitude. Animal species evolve over time, so it is not easy to identify the true nature of a species. Again, farm animals have been altered substantially by conventional breeding methods, largely without comment. Why should the fact that this process has recently accelerated cause concern? Some people will argue that, as long as the animals involved will not be caused to suffer poor levels of welfare, there is no problem about changing animals. For example, there is in principle no problem with breeding featherless chickens, as poultry breeders in Israel managed to do some time ago, as long as the chickens involved will be kept in a hot environment where they will not need their feathers to keep warm.

However, these people may also wish to stress the need for *precaution* in this area (see: **Precautionary principle**). In practice it may be difficult accurately to foresee effects on modified animals. Those who are essentially pro-modification may therefore interpret the idea of animal integrity as a precautionary attitude to rapid and radical animal modifications. Others may believe that, although alterations of animals through breeding are inevitable, there is a limit to how far we, as humans, may go in changing our fellow creatures. This view may be based on the ethical claim that we should respect nature in its own right (see also: **Environmental ethics**). An obvious issue here is whether *domesticated* animals can sensibly be considered part of nature worth protecting for its own sake. (PS)

Animal rescue

Animal rescue refers to the removal of an animal from a place of potential danger, ideally to a place where its welfare is better, although rescued animals may be euthanized in some circumstances. Rescue may involve the removal of an animal from an acute crisis, e.g. a cow that slips over a cliff, or from a chronic situation, e.g. the rescue of a collection of animals from a keeper who is unable to provide for them adequately, or the acceptance of **abandoned animals**, including those surrendered by their owners. *In situ* rescue is also possible, for example by providing additional resources for animals within a given environment, such as the provision of hay to sheep stranded by flooding. Animals may be rescued by organizations or individuals.

Animal rescue organizations are not the same as animal welfare organizations, despite the popular claim by the former to be the latter and the well-meaning intention of those involved in animal rescue in general. For example a not uncommon priority for those operating animal rescue is a

focus on saving life rather than preserving or ensuring a high **quality of life**. This can easily lead to animals being ‘rescued’ into situations where their welfare may be seriously compromised due to inadequate resources and a desire to save them from dying. The tendency of individuals or organizations to exceed their financial capacity is not uncommon, and larger rescue organizations may be called upon to take over other rescue organizations or populations as a consequence, potentially compromising their own strategic plans for animal welfare as a result. At the extremes, what may begin as rescuing a few individuals may develop into an obsessive situation or result in **animal hoarding**. (DSM)

Animal rights

Animal rights refers to the claim that animals have moral rights

This concept is primarily associated with the ethical theory first defended by **Tom Regan**, American philosopher and author of the book *The Case for Animal Rights* (1984), of which the main message is that sentient animals (‘living subjects of a life’, in the author’s own definition) possess individual rights that ought to be respected.

In the language of ethics, a right confers protection to an individual, primarily by setting limits to how others can treat him or her. Consequently, if an individual has a right, s/he is justified in making corresponding claims on others. In that sense, rights have been described as a sort of trump, a claim that overrules any other argument made over the issue. Rights can be moral or legal, or a combination of both. A distinction is also sometimes made between *active rights* (the rights to do things) and *passive rights* (the rights to have things done for or to one), and between *negative rights* (the right *not* to have something done to one) and *positive rights* (the right to have something done for or to one).

In ethics, rights is a controversial topic: there is disagreement about whether they exist at all, how extensive they are and who can hold them. Who can be a rights-holder is an essential question when discussing animal rights. Some philosophers argue that animals cannot have rights, because rights are always coupled with duties and responsibility, so that only an individual that can be held responsible can have a right. This position is, however, not compatible with the view of our society, in which newborn babies and mentally disabled persons are also granted certain rights. Even though there is a coupling of rights and duties, the right and its corresponding duty are not necessarily held by the same individual, and the distinction between active and passive rights is useful in understanding this. If a right to a certain type of action is granted to an individual (an active right), it seems reasonable that a corresponding responsibility is demanded. But if the right is passive, a right to have something done for one, the duty or responsibility falls on those that are to do something for the rights-holder. If children have rights, their adult guardians have duties towards them. The issue of animal rights can be seen in the same way: if animals have rights, then humans have duties towards animals.

Regan builds his theory of animal rights on the work of German 18th-century philosopher **Immanuel Kant**. The essence of Kant’s approach to rights is that humans have ‘an

intrinsic worth, i.e. dignity’, and that therefore they ought to be treated ‘always as an end and never as a means only’. That an individual is to be treated always as an end and never as a means can be understood in the way that it can never be justified to sacrifice an individual, even if this will lead to overall beneficial consequences. Tom Regan (1989) argues that the principle of dignity must be extended beyond the human community:

But attempts to limit its scope to humans only can be shown to be rationally defective. Animals, it is true, lack many of the abilities humans possess. They can’t read, do higher mathematics, build a bookcase or make *baba ghanoush*. Neither can many human beings, however, and yet we don’t (and shouldn’t) say that they (these humans) therefore have less inherent value, less of a right to be treated with respect, than do others. It is the *similarities* between those human beings who most clearly, most noncontroversially have such value (the people reading this, for example), not our differences that matter most. And the really crucial, basic similarity is simply this: we are each of us the experiencing subject of a life, a conscious creature having an individual welfare that has importance to us whatever our usefulness to others. We want and prefer things, believe and feel things, recall and expect things. And all these dimensions of our life, including our pleasure and pain, our enjoyment and suffering, our satisfaction and frustration, our continued existence or our untimely death – all make a difference to the quality of our life as lived, as experienced, by us as individuals. As the same is true of those animals that concern us (the ones that are eaten and trapped, for example), they too must be viewed as the experiencing subjects of a life, with inherent value of their own.

But animal rights are not necessarily defined as extensively as does Regan. A much more moderate position can still grant animals rights, albeit more limited, such as for example the right to be protected from extreme suffering or the right not to be killed for a trivial purpose. In legal terms, many countries’ animal **welfare** legislation may be seen as a protection of such more moderate moral rights of animals.

Animal rights is also an umbrella term for the more radical section of the animal protection movement

The animal rights movement draws upon the writings of both **Peter Singer** and Tom Regan’s philosophy, although only the latter is a rights theorist in the philosophical terminology. A distinction is often made between ‘animal rights’ organizations and ‘animal welfare’ (or in the Germanic languages ‘animal protection’) organizations. Animal welfare/protection advocates accept the human use of animals as long as animals are guaranteed acceptable welfare. On the contrary, the animal rights position that animals’ individual rights should be respected is generally incompatible with most, if not all, human use of animals. Consequently, organizations with an animal welfare ideology are typically reformist, accepting improvements within current practices, whereas animal rights organizations are typically abolitionists, demanding the end of animal farming, animal-based research and most other ongoing practices where non-human animals are used in the interest of humans. A small fraction of the animal rights movement maintains that the animal cause justifies the use of illegal and/or violent actions, but both Singer and Regan have dissociated themselves from that position. Animal sanctuary

An animal sanctuary is an enclosure or area which houses a group of orphaned or rescued animals; typically, the animals are kept either permanently or for an extended period of time prior to release back into their natural environment. By contrast, an animal shelter aims to provide for an animal in the short term with a view to rehoming it (see: **Animal shelter** for details relating to the rescue and rehoming of domestic animal species).

Animal rescue is not synonymous with animal welfare, but sanctuaries may provide part of the solution to future research on a range of captive species, given the rising costs of keeping animals in captivity and the concern over the use of laboratory animals. This may be particularly the case for work on captive great apes. The increasing ethical dilemma and expense of working with animals, especially apes, in biomedical facilities has prompted a need for alternative research sites. Working with animals in African sanctuaries benefits the animals, who have a better quality of life, and supports conservation efforts. It also benefits the researchers as the animals have a more natural upbringing and there are more test subjects, leading to higher-quality data. A similar argument could be applied to other exotic species living in sanctuaries, but this article focuses on the case relating to great apes, as a diverse range of benefits relating to welfare and conservation from both pure and applied research can be demonstrated very clearly.

The benefit of animal sanctuaries as a place of animal research

Historically, most of what we know about ape cognition has been discovered in biomedical laboratories from tests on chimpanzees. However, largely due to expense, most great ape laboratories outside the USA have been closed. Remaining US centres house only chimpanzees (no bonobos). The three chimpanzee subspecies have not been maintained as separate populations, and so subspecies comparisons are not possible. Laboratory populations consist almost entirely of adults, who are ageing rapidly. There is no younger generation, as the National Institute of Health (NIH) banned breeding chimpanzees for all NIH-funded projects. The majority of chimpanzees in laboratories were reared and live in simple concrete cages that were designed before any research on wild chimpanzees had been conducted. Therefore, current laboratory facilities do not provide the rich and complex environment in which chimpanzees normally develop and for which they have evolved to live.

At the same time, the remaining unprotected habitats in Africa are being destroyed and the apes living within that area are killed. The only surviving apes from such populations are infants that are taken from dead mothers to be sold as pets within Africa or on the international black market (including

Europe and the USA). The lucrative trade in these infants fuels the demise of other wild ape populations, as some try to profit by selling more infants obtained from the wild.

Most infants die within days of capture, but those that survive face a difficult life. Apes are many times stronger than their human caregivers and can not be tamed – inevitably leading to psychological and physical abuse when owners can no longer manage them.

Governments in Africa have created laws banning the capture and sale of great apes. Sanctuaries were created to offer lifelong care to those individuals confiscated as a result of such laws. Without sanctuaries, laws protecting wild apes from capture could not be enforced and thus would do little to stop the trade of live infants. The alternative would require euthanizing confiscated apes. Today there are 17 sanctuaries in 12 countries, and together they provide lifelong care for over 1000 wild-born African apes and economic benefit to many Africans.

Ape sanctuaries offer an ideal opportunity for researchers to conduct innovative research on semi-free-ranging ape behaviour, intelligence, genetics, disease/health, morphology and physiology. Sanctuaries manage apes at a fraction of the cost of laboratories. This means that non-invasive work requires only small grants (invasive work may require licensing under current legislation and so is currently less feasible in many sanctuaries). It is easy to remodel workspace for short- or long-term projects, and the cost of living in Africa is affordable compared with other sites of research. All ape species (including the largest population of captive bonobos in the world, with over 50 individuals) are represented in sanctuaries. Subspecies are maintained as separate populations, so all three chimpanzee subspecies can be compared. While breeding is controlled, the majority of individuals in sanctuaries are infants and juveniles.

Day enclosures for large social groups are areas of tropical forest that can be as large as 40 ha (100 acres). This means that the apes are reared and live in environments similar to those for which apes evolved to thrive mentally and physically – an environment that allows most animals to quickly recover from their early trauma.

Why should sanctuaries cooperate with researchers?

Researchers can make various valuable contributions to sanctuaries. In addition to helping with funds and enrichment of sanctuary animals, researchers can work with sanctuaries towards a common goal, primarily raising awareness of the species and providing material for education programmes. Research fees become another source of income for sanctuaries, helping towards management costs or improvements for research. Researchers may also donate equipment like computers and veterinary supplies. Furthermore, researchers may have expertise in areas like disease screening that could benefit the sanctuary animals. Non-invasive research, which is painless and stress free, may potentially even provide enrichment for captive populations. Many forms of primate behavioural research involve presenting non-human apes with problem-solving tasks to study their intelligence. Apes enjoy problem solving and readily volunteer to participate in such games, since these typically involve obtaining food rewards. People respect and then protect what they understand. The

results of studies on non-human apes add to our overall knowledge of great ape species and thus could lead to more respect and protection for great apes. In addition, non-invasive research in sanctuaries could set a new ethical standard for research with non-human apes, by offering researchers an alternative to working on **laboratory animals**.

For example, researchers at the Max Planck Institute for Evolutionary Anthropology and Harvard University are carrying out successful research programmes at three sanctuaries in Uganda, the People's Republic of Congo and the Democratic Republic of Congo.

The aim of this research is to identify precisely what it is about human psychology that can explain why, in many cases, humans behave so differently from other animals. Comparisons between the intelligence of bonobos, chimpanzees and human children are believed to be the only way to accomplish this goal. In trying to find out what makes humans different from other apes, we must also understand in what ways we are similar to our closest living relatives. Therefore, this type of research often identifies surprising similarities as often as it does differences between our species.

Sanctuaries recognize the importance of learning about their captive populations through non-harmful techniques that can enrich or improve the lives of their animals. Continued success will depend on whether future researchers approach sanctuaries respectfully, with a collaborative spirit and genuine interest in ape welfare and conservation. If they do, sanctuaries will become the world's finest resource for improving our understanding of the great apes, and potentially other species, in the decades to come – to the benefit of all. Animal shelter

An animal shelter is typically a place of temporary refuge (see: **Animal sanctuary** by contrast) and is often associated with **animal rescue** and **abandoned animals**. The aim of a shelter is to provide for the animal until it can be placed in more appropriate long-term accommodation. In some countries and regions, local laws prevent the **euthanasia** of healthy animals and some shelter organizations also adopt a 'no-kill' policy; in this case these shelters are in effect animal sanctuaries. While the euthanasia of healthy animals is a cause for potential ethical concern (see: **Ethics**), the maintenance of animals in a restricted environment, e.g. dogs in kennels, is a cause of **welfare** concern. This has led to a growth in research, largely sponsored by animal welfare organizations, into

methods of environmental **enrichment** for companion animals in **confinement**.

Most shelters seek to rehome animals and many invest in efforts to match an owner with a potential **pet**, although there has been little scientific validation of the efficacy of matching processes or in-shelter temperament testing. One recent report (Diesal *et al.*, 2008) suggests that the majority of unsuccessful canine rehoming are due to behavioural problems in the dog. The attendance at training classes and realistic expectation of the work involved in owning a dog also reduce the risk of return. Thus the importance of personality matching as opposed to more general owner education on the animal husbandry may be questioned. (DSM)

Animal trade

Animal products form an important part of global trade. For example, meat chickens (broilers) are the most numerous farmed terrestrial animal, with an estimated annual production of 40 billion birds – and a large proportion of this huge production is shipped around the world (in 1 million t; 1 t of poultry meat can be produced from approximately 1200 chickens):

- Exports: USA, 2.3; Brazil, 1.1; EU, 0.65; Thailand, 0.4.
- Imports: Russia, 1.3; Japan, 0.7; EU, 0.6; Saudi Arabia, 0.35; Mexico, 0.3; China, 0.3.

Global trade is influenced by national government decisions. For example, there may be legislation concerning hygiene standards or animal **welfare** standards, and individual governments may provide subsidies to producers. Produce sold on the international market must usually meet global standards – for example, to control livestock diseases or to prevent trade in endangered species.

The General Agreement on Tariffs and Trade (GATT) was drawn up by 23 countries in 1947. GATT was formed after World War II as a result of the 'Bretton-Woods Order', which also created the International Trade Organization, the International Monetary Fund and the World Bank. This Order was designed to provide an international forum that encouraged free trade between member states. The Marrakech Agreement established the World Trade Organization (WTO) on 1 January 1995. This Agreement restated the General Agreement on Tariffs and Trade (GATT) (1947 and 1994). GATT had 128 signatories by the end of 1994 and, in 2008, WTO had 153 member countries. The WTO provides a forum for negotiation of trade relations between its members,

promotes free trade and adjudicates in disputes between its members. A number of WTO side-agreements have the potential to affect animal welfare and related marketing issues: The Agreement on Technical Barriers to Trade (1994), The Agreement on Agriculture (1994) and The Agreement on the Application of Sanitary and Phytosanitary Measures (1994).

In practical terms, the WTO facilitates trade agreements between countries (which usually apply to particular products), assists enforcement of bans on trade of certain wild animals and their products, assists in the application of disease control standards (for example foot-and-mouth disease) and mediates the application of trade concessions to countries in the developing world.

The interpretation and application of these articles depends upon comparison of the 'likeness' of products; 'like' products may not be discriminated against or protected. The issue of likeness is at the core of the potential for animal product marketing problems as the GATT dispute panels have determined that, when determining whether two products are 'like' one another, they may only consider the 'end product' and not 'the way in which it was produced'. Some products – for instance, those organically produced – are demonstrably 'unlike' conventionally farmed animal products, because they meet a distinct legal standard requirement (IFOAM, UK Compendium or local legal standards) and can be marketed as a distinct product type. To demonstrate that a product meets a certain separate standard, 'certification' is usually required to discriminate this type of 'unlike' product from a conventionally farmed product.

WTO agreements may hamper local efforts to introduce legislation to protect animals, as the inability to differentiate systems of production may create disincentives to producers to adopt measures designed to improve animal welfare. Under WTO rules a country is unable to ban imports of products on ethical grounds or to insist that laws designed to protect animals or the environment must apply to imported products as well as those produced domestically. WTO prevents restrictions on imports on the basis of production method, and so countries may be powerless to stop domestic markets being undermined by imports. Additionally, EU Directive 2000/13/EC prohibits the attribution to any foodstuff of the property of preventing, treating or curing a human disease, or reference to such properties; this can impinge on animal welfare-based marketing claims, as claims of human health benefits for products emanating from, for example, free range or organic production systems may not be made. The European Commission has recognized the potentially damaging effects of WTO agreements on global moves towards animal welfare improvement and has stated its intention to 'ensure that the trend toward liberalisation does not lead to competitive reduction in animal welfare standards'.

Many countries have developed **farm assurance schemes**, and these have the potential to improve local animal welfare by offering financial (and 'ethical') incentives for producers to rear animals to raised 'standards'. These standards are sometimes significantly above the lowest denominator set by the law, and may allow local differentiation of the animal product into 'welfare friendly'. Internationally, it seems likely that farm assurance work may be undermined by the inability of systems of animal rearing offering improved animal welfare

to visibly (through labelling or through trade restriction) differentiate their products in the global market.

Many animal welfare organizations and other stakeholders see the WTO agreements as having the potential to block progress on animal protection. These organizations propose that reform of the WTO rules could help to safeguard standards of animal welfare. Some of their proposed reforms include: (i) that animal welfare be considered as a legitimate 'non-trade concern' under WTO; (ii) a generalized alteration in the legal status of animals from trade products (property) to sentient beings; (iii) allowance of trade-related measures, such as import bans on genuine animal welfare grounds; and (iv) promotion of labelling schemes to distinguish between otherwise like products that are produced to different animal welfare standards (e.g. battery versus free range eggs). (AB)

Animals (Scientific Procedures) Act 1986

For many years, live animals were used in scientific experimentation in the UK with no legal safeguards for their **welfare**, until the Cruelty to Animals Act 1876. By this Act, there were to be no prosecutions for cruelty to animals used for experiments, but they were required to be anaesthetized, used only once and then killed. The flaws were that **anaesthesia** was potentially inadequate and need not be used if it 'frustrated the object of the experiment'; there could be more than one procedure within one experiment and animals need not be killed if, again, the object of the experiment would be defeated.

Over 100 years later the Animal (Scientific Procedures) Act 1986 came into being, and it is recognized as one of the most advanced pieces of legislation safeguarding the welfare of animals used in science, and a model for other countries, although opponents of animal experimentation claim it is a 'vivisectionist's charter'. It also controls the breeding and supply of animals to be used for research and the welfare of such animals.

Control is through the granting of licences for research projects, which must be meritorious (following a cost–benefit analysis (see: **Ethics**)); the environment in which the research is to be conducted must have adequate facilities to meet animal welfare needs; and individuals involved in the research must have suitable training and qualifications. Licences are granted based on criteria, i.e. there must be no alternative to the use of animals, suffering must be minimal, with anaesthetics and painkillers being used, and the animals must be used once and killed humanely. A major feature is the cost–benefit analysis, where the cost of the animal's suffering (mild, moderate or severe) is weighed against the benefit of the research, which must have a clear objective. Mostly small rodents are used,

with larger animals and primates only being allowed in exceptional circumstances (see: **Three Rs principle**). Control and licensing is by the Home Office, through the Animals in Scientific Procedures Inspectorate and the Animal Procedures Committee. (BG)

Anthropocentrism

Anthropocentrism (from the Greek *anthropos*, human being) refers to the worldwide view and philosophical theories that consider human beings as the centre of moral considerations. The distinction is sometimes made between strong (*only* human beings have moral standing) and weak (human beings are central and other beings peripheral to moral considerations) anthropocentrism.

The traditional approaches to morality in Western society are essentially anthropocentric. This is usually seen as the outcome of the Judaeo-Christian view of human beings as having been created in the image of God and the only possessors of an immortal soul, in combination with the focus on rationality (originating in Aristotle's ethics and further emphasized during the Enlightenment).

The first seriously considered challenge to this strong anthropocentrism came with the English 18th-century writer **Jeremy Bentham**. Bentham argued that whether an individual should be considered a moral subject depended on its capacity for having subjective experiences or, in other words, to feel pleasure or pain. Such an approach to ethics is sometimes termed *sentiocentric*, and the capacity for subjective experiences *sentience*. Several modern philosophers, nevertheless, disagree with the idea that sentience provides the complete answer to the question of who should be granted moral consideration. An alternative approach is suggested by Paul Taylor, who argues that all living beings – not only sentient animals but also plants and microorganisms – have an inherent value. This is because, Taylor argues, all these beings can be seen as having 'a good of their own' which they are – consciously or not – pursuing. Other philosophers go further and criticize the focus on individuals inherent in both the sentiocentric view and in Taylor's *biocentric* view. For many environmental ethicists there is a specific value also in species, ecosystems and even in the evolutionary process itself, as well as in non-living entities. Approaches which place the emphasis on other aspects than individual beings are usually referred to as *holistic* (in contrast to individualistic theories) or *ecocentric* (in contrast to sentiocentric and biocentric theories). Anthropomorphism

In the context of animal behaviour, 'anthropomorphism' is the assumption that animals share the same thoughts, feelings and motivations as humans. In everyday life, animal companions are (and probably always have been) very often treated with extreme anthropomorphism; that is, they are treated as almost human and sometimes even as substitute children. Frans de

Waal calls this 'naive behaviourism', or taking an anthropocentric attitude to animals (Waal, 2001). Most ethologists today would probably claim that they avoid **anthropocentrism** and try to understand the animals they are studying and interpret their behaviour on the animals' terms. However, the attitude of these ethologists to the use of anthropomorphism in the interpretation of the way they study animals behave will depend on their cultural as well as their scientific training.

In parallel with the development of ethology as a science, anthropomorphism has undergone three alternating phases – acceptance, rebuttal and re-acceptance. In the 1930s, when **Konrad Lorenz** (1903–1989) began his studies of animal behaviour, which can be truly called the beginnings of **ethology**, he had no compunction in relating the ways his jackdaws behaved to the ways of people, and he used the most personal and anthropocentric language. Lorenz was followed by **Tinbergen** and Thorpe, who, among others, were more rigorous in their direct observations of animal behaviour and led the subject into a scientific discipline. Then, from around the middle of the 20th century, **behaviourism** began to make an impact when, as Daniel Dennett wrote in the *Times Literary Supplement* (16 May 1997, p. 5), 'Icy blasts of reinforcement extinguished all thought, all feeling, all mentality, and the world was a dead mechanism'. In this second phase of attitudes, anthropomorphism became a pejorative term applied to anyone who dared to believe that animals were capable of conscious thinking.

There were, however, opponents to anthropomorphism who were not as single-minded as the radical behaviourists who appeared to have inherited the beliefs of Descartes. Over 50 years, J.S. Kennedy never wavered from his published view that, 'If the study of animal behaviour is to mature as a science, the process of liberation from the delusions of anthropomorphism must go on'. Kennedy wrote about what he saw as the unwitting anthropomorphism of the **neobehaviourists**, who he defined as modern behaviourists who differed from their radical forbears in not discounting internal processes in the causation of behaviour and in not excluding some measure of cognitive activity in their study animals. He pointed to some examples of less subjective terms, such as 'scanning' rather than 'searching' and 'resisted mating' instead of 'rape', that can be usefully used by ethologists to avoid overt anthropomorphisms.

Anthropomorphism is not just an out-of-date concept – discussion about it is important because the language that is used in everyday life reflects the culture, religion and education of the society that uses it. Those who believe that anthropomorphic language is to be avoided (apart from such obvious examples as those quoted above) and that the behaviour of animals is on a totally separate level from that of human thoughts and consciousness may be considered inheritors of the Judaeo-Christian tradition, which has taught over the centuries that only humans have a soul. It is hard to escape from this cultural and religious edict, which led to the association of the supernatural attribute of a soul with consciousness, and therefore to a general denial of consciousness in animals.

Towards the end of the 20th century, with the great expansion of knowledge about the behaviour of humans and animals, as well as an increased understanding of evolutionary

theory, has come a renewed acceptance of anthropomorphism. Ethologists have been joined by psychologists and philosophers in research into the minds of animals. This multidisciplinary field of research, known as **cognitive ethology**, has resulted in a multitude of investigations into **consciousness**, **cognition**, **self-awareness** and **intelligence**, as well as on whether animals feel pain, anger, fear, love and have a **theory of mind**.

With the expanding research into animal minds has come the general realization that anthropomorphism does not disrupt scientific observation but supports the continuity between humans and animals. A strong supporter of this view is Frans de Waal who, in writing about attitudes to anthropomorphism, cites the example of his chimpanzee, Georgia, who regularly 'plays a trick' on visitors by taking a drink of water and then spraying them with it from her cheek pouches (Waal, 2001). Waal then discusses whether believing that the chimpanzee is consciously 'playing a trick' is an anthropomorphism; he argues that the most parsimonious conclusion is to assume that the chimpanzee and the humans have a cognitive similarity based on their close evolution, and he proposes the term 'anthropodenial' for the rejection of shared characteristics between humans and animals.

It is from this *milieu* that the study of the interactions between humans and animals is developing, and the investigators in this field of research may be truly called the new anthropomorphists, to whom improvements in animal welfare are of prime importance. (JC-B)

Anthrozoology

Anthrozoology is the study of animal–human interactions. The combination of *anthro-*, meaning of humans, and *zoology* first appeared in 1987 as the title of the journal *Anthrozoös*, and was later used for the name of the International Society for Anthrozoology (although *anthropozoology* would be more correct etymologically). Applied literally, anthrozoology would therefore encompass much of conservation science, animal **welfare** and applied animal ecology, but it is normally applied to studies of associations, and especially relationships, between individual humans and individual animals, rather than to interactions that take place at the population level. Anthrozoology encompasses, but is not restricted to, study of the **human–animal 'bond'**. It should logically also include unsuccessful and dysfunctional interactions (although it rarely does).

The current tradition of research into human–animal interactions is usually considered to have begun with a paper by the psychiatrist Boris Levinson in 1962, which described the effects of interaction with a dog on a young patient of his. Two decades later, by which time several research centres had appeared, particularly in the USA, Levinson addressed one of the first major conferences in this field, in Philadelphia, where he suggested four areas on which future research might focus: (i) the role of **companion animals** in human cultures from

prehistory to the present, including archaeozoology, anthropology and sociology; (ii) the effects of associations with animal companions on the development of personality, attitudes and other traits in humans, encompassing psychology and psychiatry; (iii) the therapeutic effects of companion animals; and (iv) the ethology of human–animal interactions. A further two decades on, knowledge has increased in all of these areas, and there have also been attempts to forge links between them to develop underlying theories of the human–animal 'bond', which will be covered in the latter part of this entry.

The roles of animals in human cultures have often been studied from an **anthropocentric** viewpoint and so fall outside the scope of this volume. Archaeozoology has made a valuable contribution towards our understanding of the behaviour and appearance of modern companion animals, by enabling us to trace the early course of their domestication. However, for the domestic **dog** there are currently serious discrepancies between the timing of domestication as indicated by archaeology and that suggested by the molecular biology of modern dogs and wolves. Moreover, the main focus of archaeology and historical studies has been on the contributions of animals to changes in human society, rather than on human–animal relationships. For example, the use of **horses** is cited as a major factor in the domination of the advanced societies of South America by a comparatively small number of Spaniards. At the population level, the **domestication** of animals provided opportunities for infectious agents of animals to transfer to the human host, creating such modern **diseases** as smallpox, influenza, tuberculosis, measles and cholera. Most of these appear to have originated in agricultural animals, one exception being the possible origin of whooping cough (pertussitis) in the dog.

However, relationships can occasionally be deduced from archaeological finds: the puppy found in a Mesolithic grave of 12,000 YBP, buried beneath the hand of an elderly human, was presumably a **pet**, whereas the knife marks found on some **cat** bones from mediaeval sites in Britain indicate that these animals had been killed to make cat-skin coats.

The idea that pet keeping has a positive benefit on child development is not a new one, although the underlying concepts have changed. For example, many Victorians believed that companion animals in the household could be used to teach children an abhorrence of cruelty and the value of gratitude and fidelity, emotions that pets were presumed to display towards their owners, and these attitudes have persisted in many societies up to the present day. More recently the research emphasis has switched to the effects of pet keeping on the development of **empathy**. Pet keeping in childhood seems to be reliably associated with positive attitudes towards animals in young adulthood, and there appears to be a link between empathy towards animals and empathy towards humans.

Empathy is a complex construct that is generally considered to have both cognitive ('I can imagine what you are thinking') and affective ('I can feel what you are feeling') components, and it is not yet clear precisely which aspects are most affected by pet keeping. The few studies of pets used as an intervention in educational settings have generally reported an increase in empathy, but associations between pet ownership and empathy

in children appear to be more complex: for example, one study found slightly higher empathy in dog owners, but lower empathy in cat owners, compared with non-owners. Since most family pets are chosen by parents, the latter association could be due to a personality characteristic of parents that drives both a preference for cats as pets and an inhibition of the development of empathy in children, rather than a negative effect association that a cat has on the development of empathy. Whatever the mechanisms involved, it seems likely that different species of companion animals may have different effects on emotional development, and that classifying them all as 'pets' may be an oversimplification. Moreover, research in this field has overwhelmingly focused on the development of desirable traits, and the possibility that not all pets may be beneficial for all children has barely been considered, even though links have been established between abuse of animals and violence towards people.

A variety of benefits to health have been proposed for pet ownership, and for emotional attachments to animals, and there has been much discussion about the role of pets in enhancing various aspects of human quality of life. In societies where they are well accepted, dogs act as catalysts for social interactions, especially between owners and people they have not met before, thereby expanding existing social networks. Similar effects have been observed for trained assistance dogs, such as those used as guide dogs and for people with other disabilities, and it has been suggested that these benefits may be as important as those arising from the work that the dogs are trained to do. Comparable effects due to other pet species are less well documented. Physical contact with a friendly pet has often been demonstrated to have a relaxing effect, for example by lowering blood pressure, although the undoubted stress occasionally generated by pets, for example when they misbehave, has received little research attention.

More contentious has been the idea that pet keeping may be generally beneficial to mental and physical health, and specifically protect against cardiac illnesses. Such beliefs have apparently become widespread among Western societies, but supporting scientific evidence has often been equivocal or ambiguous. Several studies in different countries have reported fewer visits to doctors among pet owners than comparable non-owners, but these findings are generally correlational rather than cause and effect. Moreover, not all have factored out the effects of additional exercise that dog ownership normally incurs. Overall, it appears likely that pet ownership is associated with slightly better health, but the mechanisms involved are still far from clear, and in considering the possible health benefits that pets might provide it is important to allow for the likelihood that unhealthy people may be unlikely to acquire pets and more likely to relinquish ownership.

Levinson was originally inspired to consider the benefits of pet keeping by the effects of the presence of his dog on the behaviour of otherwise uncommunicative children who came to him for psychotherapy, and he proposed that the dog had acted as a 'bridge' for the establishment of rapport between child and therapist. Since his pioneering work, such effects have been widely observed (see: **Animal-assisted therapy**). Interaction with dogs, in particular, has a strong motivational effect on many children with both physical and learning

disabilities, perhaps because interaction with the dog is experienced as non-judgemental and unconditionally positive.

Ethology, the study of the behaviour of animals in their natural habitat, has made only a limited contribution to anthrozoology, largely because in its modern form it specifically addresses, or at least implies, the evolutionary origins and adaptive functions of behaviour. These are not easy to unravel for domesticated animals whose behaviour has been both consciously and unconsciously selected by man. However, ethological concepts such as **dominance**, **territoriality** and **imprinting** have been widely used to interpret the behaviour of pet animals. For example, the behavioural disorders of pet cats are often divided into those of ethological origin, i.e. normal behaviour that would have been adaptive to the cat's wild ancestors but is objectionable to owners, such as spray-urination, and those that are abnormal, such as **pica**.

The concept of **socialization**, largely derived from the ethological theories of imprinting and sensitive periods, is the cornerstone of our understanding of how young companion animals learn to react to humans and other species, and how behavioural disorders can result from deficiencies in this process. In addition, ethological methods, involving the detailed observation of animals in their normal surroundings, with minimal interventions, have been used to provide detailed descriptions of interactions between pets and their owners. For example, they have been used to differentiate between the competitive play that takes place between two dogs, and the socially interactive play between dogs and people.

Theories of the human–animal 'bond'

Anthrozoology has usually been studied by specialists from one of the constituent disciplines referred to above, but at its core it is multidisciplinary, and attempts have been made to explain the keeping of pet animals, especially dogs and cats, using various theoretical frameworks, in an attempt to arrive at an explanation of the human–animal 'bond'. Some have adopted a biological perspective, for example those based upon traditional comparative zoology and ethology.

In the terminology of comparative zoology the relationship between owner and pet could potentially be classified as **commensalism**, **mutualism** or **parasitism**. Some domesticated species may have initially had a commensal relationship with man, probably as scavengers, including the wolf, the progenitor of the dog, and possibly the pig. Domestic animals primarily kept for their utilitarian value, such as dairy cattle or guarding dogs, have a mutualistic relationship with man in which costs and benefits are deliberately balanced out by the human partner. Pet keeping is undeniably costly for owners: for example, in the USA more than US\$20 billion is spent annually on pet food and pet health care. Since pets return no immediate economic benefit to their owners, some authors have classified them as **social parasites**, analogous to the cuckoo chick in the nest of its foster-parents.

Supporters of this idea have pointed out that the foster-parents presumably find it rewarding to feed the cuckoo chick, even though they inadvertently incur substantial biological cost in the process. In this conceptualization, therefore, the emotional rewards of pet keeping experienced by the owner are no defence against the charge of parasitism. However, pet keeping has two distinct differences from the cuckoo-type of

social parasitism. First, the majority of pets are deliberately obtained by their host species, although the stray cat that 'adopts' an owner could be cast in a cuckoo-like role. Secondly, pet owners do terminate the relationship with their pets if the costs become too high, especially social costs, such as the dog that bites, the cat that defaecates in the house, or the pet-induced allergies that can interfere with family relationships. Moreover, owners are aware, unlike the cuckoo's foster parents, that they can make such decisions at any time. The possession of this consciousness by one of the partners introduces complexities that may be difficult to assimilate into the conventional classifications of comparative zoology.

The ethological concept of **social releasers** has been used to explain the attractiveness of those pets that possess features redolent of those of human infants. Thus domestic cats, and some breeds of dog, have large, round, flat-faced heads and large forward-facing eyes that are superficially baby-like, and could trigger nurturant behaviour in humans. That such features are indeed preferred by humans is evident from their progressive appearance in teddy bears, which originally had bear-like proportions, and Mickey Mouse (who originally looked like a mouse). In some cases, such as the selection for flat-faced (brachycephalic) dogs such as the pug, human preference for such features has resulted in obstructions to normal breathing that constitute a serious welfare problem. However, this theory cannot account for dogs with pointed noses, or for the general preference for furry pets over hairless ones, even though the skin of the latter is more similar to that of a human infant.

Nevertheless, concepts from **sociobiology** and **evolutionary psychology** have been useful in probing the nature of the bond between owner and pet. Historically, one of the defining characteristics of the brain of *Homo sapiens sapiens* appears to be its capacity to attribute thought processes to animals. Evolving perhaps as recently as 40,000 YBP, this ability is proposed to underlie the emergence in man of complex hunting strategies, which were highly adaptive (in the evolutionary sense), and enabled both the colonization of new habitats and the displacement of Neanderthal man. Pet keeping may be a side effect of this ability, since it enables humans to impart human characteristics to animals and thereby form personal relationships with them, rather than conceiving of them simply as commodities. In this context it is interesting that pet keeping is widespread in some modern-day hunter-gatherer societies, and may possibly provide a functional benefit by providing opportunities for children to learn about animal behaviour and ultimately become more successful hunters.

Certainly the human mind has a propensity to over-attribute human thought processes to animals, and to pets in particular. Thus most pet owners express the belief that their pets are sensitive to their feelings and understand much of what they say to them, despite the current lack of supporting evidence for this from scientific study. The pet-owner relationship appears to be based upon emotions attributed by the owner to the pet, which are more consistently rewarding because they are unconditional and non-judgemental than equivalent relationships with humans, which can be both conditional and judgemental.

From a psychological perspective, the pet-owner bond is often addressed in terms of **attachment** theory. Owners

usually express strong attachments towards their pets, and feelings of grief when they die that are as acute, if not so long lasting, as those felt on the death of a close relative. From studies of the ways in which people interact with their pets, and the language that they use when talking to them, parallels have been drawn with parent-child interactions (the nurturant or caregiving part of the relationship), and the benefits of reassurance obtained from the pet may be a substitute for companionship with other adult humans. However, the charge that relationships with pets are no more than a poor substitute for deficient relationships with other people has not been borne out by research, except in the extreme cases of animal 'collectors'. Antidiuretic hormone

Antidiuretic hormone (ADH), also termed arginine vasopressin (AVP), is a nonapeptide hormone synthesized by hypothalamic neurones and secreted from the posterior **pituitary gland**. Principal functions are concerned with water homeostasis, release being triggered by increased plasma osmolarity activating hypothalamic osmoreceptors; ADH acts to insert membrane water channels (Aquaporin-2) into the kidney collecting duct, promoting reabsorption of water and secretion of a smaller volume of concentrated urine. There is also neurological release of ADH into the **brain** and there is evidence to indicate ADH effects on cognitive functions such as **memory**; it has also been implicated in the expression of a range of **social behaviour** patterns.

ADH shares a largely common structure with **oxytocin**, another nonapeptide pituitary hormone, and there is some cross-over between the actions of the two. (MRC)

Anti-predator training (for reintroduction)

Anti-predator training is the teaching of captive-reared animals to avoid predators. It is becoming a common component of pre-release conditioning prior to the reintroduction of captive-reared animals to the wild. It may be surprising that animals require experience for the development of effective anti-predator skills, since anti-predator behaviour must be functional when a predator is first encountered. However, the ability to recognize and avoid predators is often dependent on experience and has been demonstrated across taxa. Anti-

predator training typically entails the use of classical conditioning techniques to link an aversive stimulus – e.g. unpleasant stimulus such as water squirts, or environmental cues of predator presence such as conspecific alarm calls – with the presentation of a live or model predator to which the individual initially has a neutral response. This linkage quickly generates an acquired fear response to the predator or model, generally in one or two exposures. For example, in fish, if the presentation of a predatory fish (which had previously elicited no alarm) is paired with a chemical alarm substance released from the damaged skin of conspecifics, individuals acquire an alarm response.

Anti-predator training can also involve improving the efficiency of responses to predators as a result of experience. For example, young Siberian polecats (*Mustela eversmanni*) trained with a model badger presented concomitantly with an aversive stimulus (being shot with rubber bands) reduced their escape times after a single exposure. To be most effective, anti-predator training should mimic the critical features of ontogenetic processes in the wild: the stimuli used, the developmental timing of the training and the social and physical context in which it occurs must all be appropriate.

For example, training animals in a social context has the potential to amplify the effects of this intervention. Laboratory-reared rhesus monkeys became fearful and avoided snakes after observing conspecifics interacting with snakes. Moreover, when trained animals are reintroduced to the wild, they may function as demonstrators for predator-naïve individuals, which may then acquire effective anti-predator behaviour. Thus, social facilitation of acquired anti-predator skills can increase the effects of the initial investment in pre-release training by extending the benefits of training, over the short term, to a much larger number of animals and, over the long term, through the generations. (DMS)

Anxiety

Anxiety can be defined as an emotional response to stimuli associated with potential danger. Fear and acute anxiety may be very similar, both in terms of the observed behavioural and physiological responses shown and the cognitive processes involved. Anxiety, like fear, protects animals from dangers, and different types of anxiety may be classified according to the types of eliciting stimuli. The definition of anxiety may vary according to whether the approach taken is ethological (Marks and Nesse, 1994) or clinical (Dodman and Shuster, 1998). However, most animal behaviour researchers agree that fear responses are shown primarily to well-defined threats, whereas anxiety is shown in healthy animals when the source of the threat is less clearly defined.

Differences between fear- and anxiety-eliciting stimuli are matched by differences in the responses shown by an animal. Whereas fear is normally expressed as avoidance and flight in

freely moving animals, anxiety is associated with arousal, observation and cautious assessment of the threat. Stimulus-specific anxiety can be exemplified by the behaviour of a rat exposed to the smell of a cat in the familiar home environment, a stimulus associated with potential but not actual danger. The rat may initially avoid this stimulus but will soon respond with cautious, investigative, risk-assessment behaviours, which stand in sharp contrast to the flight responses observed when a rat is exposed to the actual presence of a cat. This example illustrates how acute anxious responses may be considered adaptive: they facilitate caution, information collection and planning of appropriate responses. An underlying or basal level of anxiety in the absence of obvious signs of threat is also adaptive in that it increases observation and scanning of the environment for potential danger. Such a basal level of anxiety may be especially important for ensuring the survival of both wild and extensively farmed animals, and may be exemplified by a grazing deer that periodically scans the surroundings for signs of danger.

Types of anxiety

Anxiety may be viewed and studied as either a trait (trait anxiety) or a state (state anxiety). Trait anxiety is essentially the same as fearfulness, and may be considered to be a component of **personality** (see also: **Temperament**). State anxiety refers to the emotional response that is elicited in a given situation by a specific set of stimuli associated with potential threat. There appear to be several subtypes of state anxiety in many species, because different threats are associated with different responses. The behavioural responses and cognitive processes necessary for coping with social isolation, such as escape from an enclosure and reinstatement of social contact, may be very different from the responses necessary for coping with exposure to a novel object in the home environment.

Whereas social isolation may induce **separation anxiety** in dogs, and result in attempts at social reinstatement and a number of other behavioural signs of distress, sudden reactions to an approaching stranger or exposure to a conspicuous object may induce **neophobic** responses observed as initial startle, vocalization and avoidance, followed by cautious investigation of the person or object. These examples illustrate that, although reactions to different types of stimuli may all be influenced by fearfulness, these stimuli may elicit very different responses.

The view that different types of state anxiety are independent of one another is also indicated by studies showing no correlation between different responses to potentially dangerous stimuli. This is found for laboratory rodents such as mice, where avoidance of a brightly lit novel arena may not be correlated with avoidance of an elevated open corridor, even though both situations clearly elicit state anxiety (Janczak *et al.*, 2000, 2003). The fact that an anxiolytic substance may attenuate one form of anxiety but have no effect on another supports the idea that there are different subtypes of anxiety, and suggests that these different subtypes may be mediated by different receptor systems. Different types of stimulus-specific anxiety are the products of evolutionary processes (Marks and Nesse, 1994). Anxiety subtypes reflect evolutionary adaptations to different environments and should therefore vary independently of one

another. This has the consequence that the level of anxiety elicited by different stimuli and the correlations between different responses may be species- or even breed-specific (Janczak *et al.*, 2000, 2003). The independence of anxiety subtypes allows an animal to adjust its responses in relationship to specific characteristics of the situation and thereby maximize survival in the face of potential danger.

Despite the fact that there are different types of anxiety, they are all responses to stimuli associated with potential danger and may all be affected by personality characteristics such as fearfulness, to a certain degree. Furthermore, different types of anxiety are also similar in that they are usually associated with a number of symptoms of physiological stress that may be detrimental from an animal welfare perspective. Whereas moderate anxiety may be beneficial for welfare by protecting the animal from damage, extreme or chronic anxiety may reduce welfare and productivity in domesticated animals. Certain forms of anxiety may also be a significant problem for household and sports animals and call for a combination of behavioural modification therapy and pharmacological treatment (see Dodman and Shuster, 1998). The component of anxiety that is influenced by fearfulness can also be reduced through genetic selection and by exposing animals to a predictable but varied range of stimuli, especially during the juvenile period.

Measuring anxiety

Methods for measuring anxiety, and the validity of these measures, are described elsewhere (see also: Fear) and will be mentioned only briefly here. Most models used for measuring anxiety have involved the observation of unconditioned avoidance of potentially dangerous stimuli such as novel objects, novel corridors, novel social partners and novel, brightly lit arenas (see Andersen *et al.*, 2000). Many test methods also include the registration of ethological parameters such as vocalization or other species-specific anxiety-motivated responses. The **approach test**, which may involve different stimuli, may be either a test of anxiety if the object is merely a novel object or a test of fear if the stimulus is something the animal has had uncomfortable experience with in the past. The **open-field test** is a typical behavioural model that induces a state of anxiety by exposing animals to a novel arena. (AMJ)

Apathy

Apathy can be used to describe abnormal, maladaptive, reduced activity, lack of interest or concern (i.e. indifference), and a lack of feeling and emotion (impassiveness). Although the term is often used in animal behaviour work to refer to a state of general behavioural **depression** (or suppression), the relationship between apathy and depression in humans appears to be disease-specific and generally uncorrelated. Apathy is considered to be a neuropsychiatric syndrome that is clinically distinct from depression. Human apathy is mediated by frontal lobe systems, highly prevalent in neurodegenerative diseases and significantly correlated with cognitive impairment (Levy *et al.*, 1998).

Apathetic behaviour (i.e. few, if any, signs of vigour or excitement) tends to occur when animals are kept in environments that are inappropriate, offer few challenges or in which the animal has little control. Sows confined for long periods within small pens/stalls demonstrate inactivity and reduced levels of responsiveness to stimuli (Broom and Johnson, 1993). Animals that are unable to avoid an unpleasant stimulus (e.g. aversive conditions) initially try to adapt via the psychological process of **habituation**. If unsuccessful they may enter an apathetic state, described by some as **learned helplessness** (i.e. they learn that they have no control over the stimulus) or **learned hopelessness** (i.e. they predict that they cannot eliminate the stimulus), whereby they remain distressed but no longer attempt to make appropriate responses to improve their situation via escape or avoidance. Since animals exhibiting such behaviour provide a cause for concern, it is important to distinguish apathy from resting contentment.

It is possible that the tendency for an animal to become apathetic may be related to its personality, temperament or coping style, with those individuals identified as passive, or those that internalize their response to **frustration**, more likely to exhibit this behaviour. However, to date there has been little animal welfare research specifically investigating apathetic behaviour beyond that associated with the learned helplessness paradigm in psychology. (DSM, GC)

Appeasement

Appeasement refers to the gestures used to reduce social tension in order to avoid violence. Traditionally, the term has been used to refer to what are commonly referred to as signs of **submissiveness** issued by lower-ranking animals towards others (often described as more dominant animals as a result) to discourage attacks or aggression when there is competition

for access to a resource. As such, appeasement may be seen as integral to the maintenance of social hierarchy. However, it is now recognized that some species appear to display a wider range of behaviours that tend to have more general derousing effects in a greater variety of contexts, and that these behaviours may not necessarily be issued by the typically subordinate individual. In dogs these behaviours have been popularly referred to as 'calming signals', and include gestures such as head turning, blinking, yawning and slow movements; these can be shown in a range of situations involving stress in a social context, even if there is no resource dispute, e.g. when an owner appears angry with their dog for not coming when called. Some authors prefer the term 'appeasement' to submission or **submissiveness**, because it can refer not only to a wider range of behaviours, but also because the latter can seem to imply that the animal has awareness of or is motivated by its social standing, as opposed to avoiding conflict, which can be determined objectively without inference about the cognitive state or capacity of the individuals concerned. (LMD, DSM)

Appetitive behaviour

Appetitive behaviour is the variable, flexible, searching phase of a behavioural sequence, indicative of the need or desire to achieve a certain goal. Appetitive behaviour is usually followed by **consummatory acts**, which are more invariant or fixed and usually lead to termination of the behavioural sequence. Appetitive behaviour may function not just to obtain a goal, but also to obtain information about the location or availability of a resource and its quality for future requirements. It therefore serves an important role in information gathering.

A typical example of appetitive behaviour is the searching for food as a part of **foraging behaviour**. The consummatory phase of foraging behaviour is the ultimate eating that ends the foraging sequence. In this context appetitive behaviour and consummatory behaviour come in a variety of forms, depending on the species. Examples of appetitive behaviour include: (i) the hunting of feline and canine species; (ii) the ground-pecking and -scratching of poultry; and (iii) the rooting and nosing of pigs. Examples of consummatory eating behaviour include pecking, biting, chewing or swallowing whole.

Foraging activities are influenced by both internal factors, such as nutritional requirements, and external factors, such as social factors, and the distribution and availability of food. In general, hungry animals spend less time on appetitive behaviour and are less selective in their choice of food. Some farm animals show **contra-free loading** (i.e. they continue to put effort into performing foraging activities even though food is freely available), but less so when they have been deprived of food. Social factors that influence appetitive behaviour include, for instance, competition for food and **social facilitation**. Social facilitation is commonly described as the increase in frequency or intensity of particular responses already in the animal's repertoire, when shown in the presence of others engaged in the same behaviour. It has been found that a satiated domestic chicken, when seeing another chicken feed, will show increased consummatory eating behaviour but an even more marked increase in appetitive pecking at the food (Keeling and Hurnik, 1996).

In farm animals food is usually readily available, either continuously or in discrete meals. Delivering food in meals can affect both quantity and quality of appetitive behaviours, through anticipation and frustration. Animals, for example, that can anticipate the delivery of food through external cues but experience a delay between cues and the actual arrival of food, often develop stereotypic behaviours that originate from appetitive behaviours (see: **Stereotypies**) (Rushen *et al.*, 1993). Furthermore, by giving animals like sows food in meals the full performance of appetitive behaviour is often thwarted, which can result in the performance of stereotypic behaviour after feeding.

Other examples of appetitive behaviour include courtship as part of **sexual behaviour** and nest building as part of **reproductive behaviour**.

Intensive husbandry conditions can put constraints on the performance of appetitive behaviour by not providing the relevant stimuli or commodities. How this affects the animal and its welfare depends on the actual causation of behaviour. For instance, some appetitive behaviour sequences are clearly goal-directed. A goal is defined as the external situation that may elicit the behaviour and the achievement of which will bring the sequence to an end. So, providing an animal with the goal (e.g. food, a nest) makes it unnecessary for that animal to perform the accompanying appetitive behaviour to achieve that goal. This probably has no negative impact on the welfare of the animal. In contrast to goal-directed appetitive behaviour, the performance of some other appetitive behaviour is strongly internally motivated and probably rewarding in itself. Thwarting of such appetitive behaviour is more likely to have a negative impact on welfare because the animal still has the need to perform it, irrespective of the consequences.

One example of such a behavioural need is **dust-bathing** behaviour in laying hens. The function of dust-bathing behaviour is to remove feather lipids and maintain the plumage condition. In the initial, appetitive phase of dust bathing, a hen tosses the dusty substrate into her feathers with vertical movements of her wings. In the next, consummatory, phase she rolls on her side and rubs the dust thoroughly through her feathers. The dust-bathing sequence ends with the hen standing up and shaking her body vigorously. An essential part of the release mechanism for dust bathing is the build-up of internal motivation in interaction with a pronounced diurnal rhythm. In the absence of a dust-bathing substrate or even a plumage, a hen will still perform the appetitive phases of dust bathing (even if in a 'vacuum' form (see: **Vacuum behaviour**)). Thus, complete prevention of dust bathing is likely to impair a hen's welfare. Whether the performance of vacuum dust bathing is less satisfying than dust bathing with a full substrate is less clear. Long-term deprivation also changes the quality of the behaviour; the time spent on the appetitive tossing phase decreases, while the consummatory rubbing phase becomes more predominant.

An example of how goal-directedness determines the termination of a behaviour is seen in the nest-building behaviour of sows (e.g. Jensen, 1993). The appetitive phase consists of nosing, rooting and pawing potential nesting material and is mainly elicited by an internal factor, the level of prolactin. In the subsequent consummatory phase the sow gathers and arranges the material to construct the nest. Sows that do not

have nesting material at their disposal do not proceed to the consummatory phase but persist in performing appetitive behaviours. Thus, although the onset of the appetitive phase of nesting behaviour is mainly caused by an internal factor, externally derived factors – e.g. the presence/absence of substrate – certainly play a role in proceeding to the consummatory phase and termination of the nest-building sequence.

Thwarting of appetitive behaviour, especially foraging behaviour, can lead to stereotypic behaviour in several farm animal species. These stereotypic behaviours vary in form and time. Mason and Mendl (1997) pointed out that species differences in natural foraging behaviour might underlie these differences. Pigs and chickens under semi-natural conditions spend most of their day searching for food. Pigs perform rooting and nosing of the ground for up to 50% of their day, whereas chickens in the wild spend almost 50% of their time ground-pecking and -scratching. Both species have a very broad diet, usually with a patchy distribution. In such patch-feeders, feeding enhances foraging; bouts of appetitive behaviour will naturally be alternated with bouts of consummatory acts. When food is clumped, there is a clear advantage in increasing the intensity of foraging when food is discovered. Most carnivores also spend a lot of time foraging, which usually involves a large amount of physical effort (e.g. hunting in hyenas, cheetahs). However, a foraging sequence usually terminates once they have caught the prey. This might explain why pigs and chickens perform most stereotypic behaviours after feeding while carnivores, such as mink, perform them before feeding. Thus, it is not surprising that hunting animals tend to pace, whereas other species show oral stereotypies.

Applied ethology

Applied ethology is the study of the behaviour of animals in relation to their management or welfare. Behavioural studies may be conducted with any animal used in some context by humans, for example in laboratory research, in entertainment, as companions or for food. Applied ethology is the application of our knowledge of the behaviour of such animals from these studies, usually in order to improve their management. (KT)

Approach test

The approach test involves the observation of an animal's approach and avoidance of a clearly defined object and is used to quantify the forces favouring approach relative to the forces favouring avoidance. Miller's model of approach–avoidance conflict provides a conceptual framework for interpreting behaviour in the approach test (see also: Fear). Although the approach test has often been focused on quantifying fear or anxiety, similar methods can also be used to measure the strength of a number of emotions or motivations, depending on the design of the test. Modifications of the approach test can also be used to study cognitive processes such as learning (see also: Cognition; Conditioning). The strength of the approach test is that it is flexible and can be designed to measure a large number of different psychological characteristics. It also allows the experimenter to exert some control over the effects of variables that are potentially confounding.

Forces favouring approach include hunger, thirst, curiosity, attraction to familiar stimuli in an unfamiliar environment or attraction to mildly unfamiliar stimuli in a familiar environment. Forces that favour avoidance include fear, anxiety, pain, frustration and boredom. The original work of Miller involved conditioned behaviour in rats. Rats were first trained to perform an operant response in order to receive a food reward and then punished with an electric shock while performing the operant response. He showed that approach and avoidance tendencies could be independently manipulated. Varying the duration of food deprivation affected the approach tendency, and varying the strength of electric shock altered the avoidance tendency. This illustrates that the different factors influencing approach and avoidance tendencies can be consciously incorporated into the design of an approach test. This would increase the likelihood that the test actually measures what the experimenter is interested in measuring.

Different forms of the voluntary approach test are commonly used to quantify fear and anxiety in animals. This test involves the placement of a test animal into a corridor and the quantification of the time spent close to or in contact with a human or inanimate object at one end. It has high internal validity for measuring fear of humans and fear of an object associated with pain. It is also internally valid for measuring the anxiety induced by exposure to a novel object or area. Avoidance of dangerous and potentially dangerous stimuli is one of the most fundamental aspects of fear and anxiety, respectively. This is mainly indicated by the fact that aversive experience with an object increases subsequent avoidance of the object in most species and that most species also initially avoid novelty. It has also been shown that forced exposure to novelty and objects associated with pain induces behavioural signs of risk assessment and acute fear. Forced exposure also results in physiological and neuroendocrine responses characteristic of fear and anxiety. These symptoms of fear and anxiety subside when an animal is no longer exposed to the aversive stimuli.

Because the strength of fear and anxiety increases with increasing proximity to an aversive object, it is possible to validate independent measures in relation to this gradient. Ethological, physiological and neuroendocrine indicators of increased fear should increase with increasing proximity to the object or person, and decrease with increasing distance.

Measurement of avoidance as an indicator of fear also has external validity in many species because it is often predictive of fear responses to similar stimuli outside of the test situation. This has been shown for pigs, where animals that avoid humans in standard tests are subject to signs of chronic stress when they are regularly exposed to humans (Hemsworth *et al.*, 1986; Janczak *et al.*, 2003).

Fear of humans or novelty-induced anxiety causes avoidance, whereas appetitive motivation and curiosity cause approach. The time that the test animal spends at different distances from the stimulus can be used to quantify the strength of fear or anxiety relative to the strength of emotions favouring approach. Alternative measures are the latency to contact the stimulus and the time spent in contact with it. A frequently cited but easily solved problem with these tests is the concern that animals may simply ignore the stimulus. Although this is clearly a question of calibration in designing the test, it does not necessarily cause interpretational problems; increasing the strength of the approach tendency can solve this problem. Food can be offered to food-deprived animals or contact with a conspecific can be offered to highly social species. If the rewarding stimulus (food or social partner) is placed at the same end of the corridor as the avoided stimulus, it should be possible to quantify the balance between approach and avoidance tendencies in animals that would otherwise ignore the feared human or object by itself.

Because of this possibility for standardizing effects of social-reinstatement tendencies in the approach test, a properly designed approach test is not subject to the same interpretational problems that are inherent in the **open-field test**. In the latter, it is difficult or impossible to standardize such confounding effects on behaviour. It is interesting to note that variance in approach and avoidance tendencies is mainly a product of the strongest and most variable motivations. Because fear and anxiety are powerful emotions, they initially inhibit curiosity-motivated, hunger-motivated and socially motivated responses. Variance in approach and avoidance therefore normally reflects fear and anxiety in animals that are exposed to humans or novel objects. However, if animals are tested in the absence of fear- or anxiety-inducing stimuli, the influence of these emotions can be negated and modifications of the approach test can be used to measure the relative attractiveness of different stimuli that elicit approach responses (**see also: Preference**). This modification of the approach test has been used for measuring effects on social reinstatement responses in a number of species (Marin *et al.*, 2001). In conclusion, different forms of the approach test, if properly designed and validated, should be very useful for measuring a number of emotions and motivations in a range of different species. Approach–avoidance conflict

Approach–avoidance conflict refers to the inferred motivational state of an animal exhibiting behavioural inhibition when presented with either a new stimulus of potential significance or a situation of ambiguous valence (desirable and undesirable characteristics). It is used in many experimental models to assess ‘anxiety’. For example, the time spent in approach–avoidance conflict is often recorded in tests such as the **elevated plus-maze**, the **light–dark test** or **open-field tests**, which may be used to assess the anxiolytic (anti-anxiety) effects of chemotherapeutic agents. Ambiguous situations can be used to assess the potential aversiveness or attractiveness of a given stimulus by combining it with stimuli of opposite valence and varying intensity, in order to determine at what point approach avoidance is induced and/or overcome (**see also: Choice test**). In response to approach–avoidance conflict, animals may express **ambivalent behaviour**, **displacement behaviour** or signs of emotional **frustration** (such as **aggression**). (DSM)

Aquinas, Thomas

The Aristotelian (384–322 BC) view that human beings are unique in their possession of the faculty of reason and that there is a natural hierarchy of life forms is amalgamated with the teachings of the Catholic Church in the works of leading Church father St Thomas Aquinas (AD 1225/1227–1274). While non-human animals occupy a higher status than mere vegetative life forms, Aquinas believed that they are morally inferior to human beings because they are without reason and, hence, do not possess free will. Furthermore, he believed that human beings are ‘intellectual creatures [who] hold the highest place, because they approach nearest to the divine likeness’. Aquinas’ view of ‘dominion over Nature’ has been interpreted as giving license to human rule over and subsequent exploitation of animals ‘either by killing or in any other way whatever’.

Upon closer analysis, it is found that Aquinas did not think that we could *treat* animals as we wanted. While ‘the love of charity’ does not extend to ‘irrational creatures’, Aquinas believed that there were proper ways of interacting with animals. In his view, the mistreatment of animals did not constitute a harm to the animals themselves. Instead, the caveat against abuse or neglect reflected his fear that mistreatment of animals would result in cruelty to other human beings.

In contrast to Aquinas, other Christian thinkers like St Francis of Assisi have extended direct concern to animals. (RA)

Arousal

Arousal is a state of psycho-physiological activation that determines the responsiveness of an individual to environmental stimuli. From a behavioural point of view, arousal is characterized by increased alertness, sensory sensitivity and readiness to respond to stimulation through faster cognitive processing and motor response. Arousal results from the activation of several neurobiological systems (i.e. the reticular activating system in the brain stem, the **autonomic nervous system** and the endocrine system), involving the action of various neurotransmitters such as **acetylcholine**, **norepinephrine**, **dopamine** and **serotonin** in order to meet the energy requirements for the behavioural response and to maintain **homeostasis**. From a physiological point of view, this activation leads to an increased heart rate, blood pressure and the production of **corticosteroid**. Arousal is closely related to other concepts such as **stress**, **anxiety**, **attention** and **motivation**.

Part of the response to stress is, for instance, elicited by the emotional arousal that arises from environmental stimulation. Emotional responses arise when the individual evaluates a challenging event and then influence its adaptive response through various ensuing arousal levels. The study of emotion in animals has recently been approached, for instance, in sheep through an original framework derived from appraisal theories developed in human cognitive psychology. It hypothesizes that particular emotions stem from a particular combination of a limited number of criteria (i.e. suddenness, familiarity, predictability, pleasantness, conformity with expectation, controllability). From a welfare point of view, acting on such criteria could, for instance, allow reducing negative emotions in animals and thus lowering of emotional arousal and stress.

Arousal is a major aspect of many learning theories. The Yerkes–Dodson law, for instance, predicts that there is an optimal level of arousal for learning to occur, depending of the nature of the task to be learned. A mild stress would increase attention and thus facilitate learning, but by contrast too low or too intense stress/arousal would have detrimental effects. Müller and Pilzecker have also proposed a ‘perseveration–consolidation’ hypothesis, which has been supported by several human and animal experiments showing that emotional arousal enhances long-term memory of immediately preceding neutral stimuli, through the activation of the amygdala. Arrhythmia

A cardiac arrhythmia may be defined as any deviation from the normal cardiac rhythm or heart beat. Arrhythmias may present themselves as an increase (tachycardia) or decrease (brady-

cardia) in rate or as a chaotic motion (fibrillation) in the cardiac muscle. There are multiple causes of arrhythmias, and prognosis ranges from innocuous to fatal depending on the type and intensity of arrhythmia present and whether or not treatment is sought. (RM-F)

Artificial insemination

Artificial insemination (AI) involves the collection of semen from a male animal and its introduction by artificial means into the reproductive tract of a female, with the intention of achieving conception and a subsequent pregnancy. Artificial insemination was the first of what may be termed assisted-breeding technologies to be developed, with anecdotal accounts referring to its use with native Arab horses dating back as far as the 14th century. The first documented experiments in mammals were performed in the 1780s on dogs by the Italian physiologist Spallanzani, who reported the live birth of three pups born to a bitch he had artificially inseminated with a syringe 62 days previously. However, AI remained something of a scientific curiosity throughout most of the 19th century and it was not until the later part of that century and early 20th century, as part of a new scientific approach to agriculture, that AI began to be established as a technique for livestock **breeding** and improvement.

Successful artificial insemination is dependent on three distinct stages – collection of viable semen from the male, generally followed by a degree of semen processing and frequently by a short- or long-term holding period, and finally introduction of semen to an appropriate site within the female reproductive tract at an appropriate time in the reproductive cycle.

Ejaculated semen can be collected from many domestic livestock breeds by use of an artificial vagina (cattle, horses, sheep) or by manipulation (pigs, dogs, poultry, fish species), but these methods are restricted to species that are both safe to handle and are to some degree trainable. Excessive use of an individual may raise **welfare** concerns, as musculoskeletal injuries may occur as a result of excessive mounting and dismounting. For recalcitrant domestic or wild species semen collection can in many instances be accomplished under sedation or full **anaesthesia** by **electroejaculation** using rectal probes. Electroejaculation may also be used for valuable males whose reproductive function has been compromised by injury or illness, and in such cases pharmaceutical techniques have also been used to stimulate semen release. However, the routine use of electroejaculation – particularly in the absence of sedation – does raise welfare issues. Surgical and post-mortem collection has also been used, by taking sperm directly from the vas deferens or epididymis.

Following collection, procedures most often involve a dilution stage where the ejaculate is extended with a diluent designed to both maintain short-term viability and dilute the semen to allow greater efficiency of usage. Medium- or long-term storage of the semen may be undertaken at this stage either by chilling to temperatures above 0°C or by cryopreservation in liquid nitrogen, but the success of chilling or freezing processes is highly species-dependent and in many cases subject to individual variation within species. Deposition into the female tract must be timed to coincide with ovulation, either during the course of a natural cycle or by giving

exogenous hormones to stimulate timed ovulation. The site of semen deposition is usually into the uterus, by canulation of the cervix.

Many domestic species will allow insemination when in oestrus, but wild species will require sedation or full anaesthesia to ensure safety and compliance. In some species, e.g. sheep, the morphology of the cervix makes canulation difficult and insemination has more commonly been performed using a surgical technique involving laparoscopy, which can be performed under local anaesthetic; this inevitably increases the level of training and experience required in the inseminator, increases costs and raises welfare issues for the animals concerned. Where the numbers of sperm available for insemination are low or semen is generally of poor quality, deep intra-uterine techniques have been developed in which a catheter is guided using either an endoscope or ultrasound to place reduced numbers of sperm adjacent to the utero-tubal junction at the top of the uterine horn.

Artificial insemination has four major advantages over natural covering: (i) it maximizes the use of superior males; (ii) ejaculates can be extended and divided to obtain the highest number of insemination doses from each ejaculate; (iii) the procedure overcomes geographic limitations, allowing semen to be shipped to females; and (iv) chilled and frozen semen also overcomes temporal restrictions as semen can be collected and stored on a short- or long-term basis before use. The increased availability of the highest-quality males has driven the dramatic increases in production seen, for example, in the dairy industry since the introduction of AI. AI has also had a major role in the reduction of venereal disease, by restricting direct contact between male and female animals and by allowing semen to be held while animals complete quarantine periods. However, semen is itself a route of infections, and international AI programmes are potentially also at risk of spreading venereal diseases if males are not fully screened.

Artificial insemination plays an increasing role in conservation programmes for endangered species, making breeding plans involving small, geographically isolated and often valuable captive populations simpler and more successful. The establishment of frozen semen banks can extend the reproductive life of individual males and thereby effectively increase breeding population size while also acting as an insurance against catastrophic loss. Frozen semen banks also have a therapeutic role in overcoming infertility and are of increasing importance in maintaining ever-expanding numbers of genetically modified animals, particularly laboratory rodents. The use of AI also enables breeders to avoid behavioural incompatibilities and to achieve pregnancies in species where correct sexual and mating behaviour is either insufficiently known or difficult to recreate under captive conditions, thereby preventing possible injuries consequent on attempting to pair animals in an inappropriate way or at an inappropriate time.

Assistance animal

An assistance animal is one that is used to facilitate an activity by a human who is otherwise impaired in this action. Many assistance animals are trained to complete tasks in relation to a human disability. Such animals are provided to increase the

safety, mobility and/or independence of their human companions. Examples of tasks include guidance when walking (guide dogs for the blind), warning of imminent seizures (seizure-alert dogs), informing the human of important sounds (hearing dogs for the deaf) and assistance with other, more general tasks related to mobility (**service** or assistance animals, typically dogs or monkeys). There is growing interest in the use of **companion animals** in the management of mental health problems, including autism and learning difficulty, where they may act as a catalyst for improved communication. Attachment

The theory of social attachment comes from psycho-ethology and provides a framework for the discussion of affectionate relationships. It was developed in the 1950s by Bowlby and then later on by Ainsworth in human babies, and refers to the strong emotional bond that develops between infant and caregiver and that provides the infant with emotional security. The concept of attachment is used to describe the mechanism that leads to the establishment of the relationship, but also most frequently the relationship itself. The result of the attachment process in mammals is thought to be the equivalent of the **imprinting** described by Lorenz in birds. Imprinting indeed occurs during sensitive developmental periods (i.e. **critical period**), and specific behaviours are then restricted and directed towards particular individuals only.

However, while imprinting seems to be almost instantaneous, the attachment mechanism in mammals appears to be slower. An individual can develop several attachments during a lifetime: a primary attachment towards the mother (or the father) and secondary attachments such as attachment between youngsters or adults (e.g. sexual partner), which are weaker than the previous one. Several definitions of attachment have been suggested since 1958, but the overall specific characteristic of the attachment mechanism is that it results in the establishment of a relationship which is emotional, selective and reassuring. The attachment figure (e.g. the mother) has an effect on the emotional reactivity of the subject. Furthermore, even if several attachments can exist, each of them is supposed to be unique in its expression. Finally, the attachment figure has been shown to act as a base of security from which the subject could gain reassurance during challenging situations and in the presence of which s/he will show a greater propensity to explore his/her environment. If attachment is described as an enduring **bond**, it is not clearly defined whether it will last a lifetime after a long separation period.

At birth, social attachment is based on innate behaviours displayed by the young (e.g. tendency to follow, vocalizations), which will be directed towards the mother or any caregiver and then enable the development of the affectional bond. According to the ethological point of view, the behaviour of the neonate can be understood in terms of adaptive value as it

ensures that the young will get food, warmth and protection from its mother. The process of attachment is defined as being based on internal **reinforcement**.

Ethologists thus emphasize the biological and genetic basis of development, even though they do not dismiss the implication of some learning. The ethologists' attachment theory has been subjected to several controversies. From a behaviourist perspective for instance, learning and feeding would have a central role in the attachment process: the newborn would learn to prefer their mother as they associate her with the feeding activity (see: **Behaviourism**). This hypothesis has been rejected following the work of Harlow and colleagues on monkeys, who showed that attachment behaviours such as contact or security seeking occurred even without the provision of food by the figure of attachment. According to the behaviourists, **operant** conditioning based on the reciprocal responsiveness between the mother and the young could explain the attachment process. This implies that the attachment behaviours of the young are reinforced by food and positive interactions, and in contrast that they would be decreased by negative interactions. According to the operant conditioning theory, a young individual that had been mistreated by its caregiver should not exhibit attachment behaviours as they are not reinforced. This hypothesis has also been ruled out by studies in animals showing that young animals continued to seek physical contact from their mother even though she might reject them. Discomfort or **distress** states such as hunger, thirst or **fear** have been suggested to facilitate the expression of attachment behaviours.

Recognition of the partner is an essential prerequisite for attachment to occur. In the context of maternal attachment, for instance, the young individual needs to learn the characteristics of the figure of attachment to be able to recognize it and subsequently express a preference. Recognition is conditioned by exposure to the characteristics to be learned (i.e. contact), learning and memorization. Complex interactions between different hormones and neurotransmitters that are influenced by genetic and environmental factors underpin attachment through the promotion of contact seeking and social behaviours and the facilitation of sensory learning, social memorization and the establishment of preference. **Oxytocin**, vasopressin, opiates and **norepinephrine** have been proved to play major roles in this process. These neurochemicals have also been shown to be implied in the expression of attachment, such as separation-induced **vocalizations**.

A behaviour can be considered as being indicative of attachment if it is expressed more often and more intensively towards a particular individual than towards any other. Several criteria should be met to conclude the existence of an attachment relationship. The figure of attachment should elicit the expression of a preference compared with any other familiar individual. It should also elicit contact seeking, separation distress, appeasement following reunion and should be used as a secure base.

A measure of attachment combining all those elements has been developed by Mary Ainsworth in human infants. Her Strange Situation Test is carried out in a novel environment and based on a succession of eight periods consisting of separations from and reunions with the caregiver, combined with exposure to a stranger. The use of the Strange Situation

Test is not restricted to the field of human psychology. The nature of the bond that can exist between domestic animals and humans can indeed also be studied using adapted versions of this test. Recent results in dogs based on this paradigm give support to the hypothesis of the dog-human attachment. Attachment theory has thus been suggested for use as a framework with regards to canine **separation anxiety**.

Other studies have also tried to assess the possibility of an attachment between farm animals and humans using, for instance, artificially reared lambs as a model. Test situations have been developed to assess exploration of a new environment (secure base hypothesis) and feeding activity in the presence/absence of the caregiver, as well as preference for and reaction to separation from and reunion with the caregiver. Treatment procedures use various levels of food provision and contact with the caregiver, and test situations have been carried out under different levels of satiety to help differentiate between a conditioning versus attachment hypothesis. Even if no definitive conclusion can be drawn, results suggest that attachment could indeed occur between farm animals and humans. (SL)

Attention

Despite William James' assertion in his *Principles of Psychology* in 1890 that 'every one knows what attention is', measuring or enumerating attention is complex because it encompasses subjective mental states of consciousness and awareness. James stated: 'Focalization, concentration of consciousness are of its essence. It implies withdrawal from some things in order to deal effectively with others.' Definitions usually centre around the idea that computational constraints prevent the brain from processing all incoming sensory information simultaneously; the purpose of attention is to permit prioritization of important information by restricting what input is noticed, processed and stored in memory.

Attention is a necessary condition for learning to take place and so underpins all sorts of processes vital to animal survival. In models of classical **conditioning**, unconditioned stimuli that are unexpected or surprising attract more attention and so have greater associative strength; when unconditioned stimuli are paired, an attention-grabbing element may block or overshadow learning about the other stimulus. Novelty and fast changes are responded to so readily because they denote new information that may require further analysis. Ability to pay attention will decrease with task difficulty or strong distracters. **Habituation** occurs when a stimulus no longer attracts attention. Habituation will be slow and distraction more difficult from highly motivated activities or stimuli that relate to fulfilling a behavioural need – such as finding food or materials to make a nest – because these are allocated a high priority for attention. Barren environments provide little input on which

to focus attention and may cause maladaptive or redirected behaviour in captive animals. Rats, mice and macaques reared in impoverished or socially isolated conditions have demonstrated over-excitement or repetitious, unvarying responses towards test stimuli as well as failure to habituate to novel or irrelevant input. Environmental **enrichments** for zoo, laboratory or **pet** animals will be most successful where these continue to attract attention over a long period, stimulating **foraging and exploratory behaviours**.

Animal behaviour often appears to represent adaptations to a limited attentional capacity. Animals attend to certain important features or dimensions of the environment while ignoring others (selective attention), discriminate more accurately when able to focus on one rather than two stimulus dimensions (divided attention) and find ways to reduce the demands of tasks requiring prolonged concentration (sustained attention). Other adaptations such as camouflage and sit-and-wait predation work precisely by avoiding drawing attention. Exploring attention in humans has relied heavily on verbal reporting of experience, making the design of analogous tests for animals challenging. Attributing an attentional cause to behaviour generally relies on carefully controlled laboratory testing, but this can often make sense of behaviours in a natural context.

Selective attention

This is a mechanism for coping with limitations in processing ability by focusing on the most salient features. Its study generally measures the ability to focus on a stimulus while avoiding other, distracting information. Discrimination tasks indicate that animals direct their attention to certain features to form a 'search image' of prey or food items. Where prey is cryptic, the task is harder and may require a very specific search image that restricts selection to one prey type. This could mean that other, palatable food is ignored; indeed, attentional models of capture efficiency appear to best explain real foraging patterns and priming effects. Priming effects describe the increase in detection speed or accuracy seen when a cue indicates the timing or position of a target's appearance. Focusing attention on an area of space or time reduces distractions, resulting in improved performance compared with un-cued or miscued trials. Exposing pigs to task cues or a novel environment between learning and completing a maze task adversely affected recall, suggesting that distractions that redirect attention during the retention of learning can interfere with **memory** storage or retrieval.

Divided attention

This examines the capacity for, and constraints on, performing more than one task simultaneously. In nature, it is rare that an animal will be able to attend exclusively to one stimulus. Animals must find or select food while monitoring the presence of predators, group-mates or rivals. Divided attention has been most extensively explored in animals using delayed matching to sample tasks where subjects – usually birds – are taught to recall which of two stimuli matches a stimulus shown briefly beforehand (limiting the time available to process all the information). In separate sets of 'element' trials, the subject is taught to match a single dimension such as colour or shape. In compound trials, the stimulus to be matched presents a

'compound' of both learned shape and colour. As before, the comparison stimuli in these trials consist of only one dimension, and only one stimulus provides a match. Performance is consistently poorer on compound trials, where attention must be shared between the two features in order later to select the one to be matched. Reduced performance on divided attention tasks is reliably associated with cognitive changes related to ageing.

Sustained attention

This describes the ability to concentrate on one thing for a prolonged period. In pet dogs, it has been suggested that a deficit in attention span appears to cause behaviour problems analogous to those seen in human children with attention deficit hyperactivity disorder (ADHD). In wild animals, sustained attention is most widely studied in vigilance behaviour. Like selective attention, vigilance enhances information processing by directing alertness towards certain stimuli. In sustained attention, the focal stimulus is a rare and unpredictable event such as the appearance of a predator. The **central nervous system** cannot focus indefinitely on any one task: a decrement in detection ability is seen over time and occurs faster with more difficult tasks, such as spotting well-camouflaged predators or prey or learning new tasks. Recovery of vigilance requires rest and one advantage of group living is to increase the proportion of time individuals can spend engaged in resting, foraging and other behaviours. Time spent vigilant is commonly inversely proportional to group size. Ducks intermittently 'peek' during rest to check for predators, and individuals' rates of scanning increase as group size falls.

Attention is vital to higher cognitive processes such as **social learning**, where the presence or activity of a **conspecific** increases the salience of one stimulus over another, leading to its exploration or manipulation. Hens' maternal displays actively attract chicks' attention to profitable food and away from harmful or unprofitable items. If a novel behaviour is to be transmitted, it must attract observers' attention. In order to imitate, an observer must focus on another individual's movements throughout a demonstration in order to replicate its actions. Indeed, experimental findings show that marmosets watch for longer when a conspecific is engaged in a food-finding task rather than in exploration.

Most mathematical modelling of attention is based on the assumption of resource constraint but, even without it, recent work suggests that limiting attention can be an optimal strategy. Attending preferentially to stimuli whose predictive relationships are unknown is statistically efficient regardless of how much else can be processed. Modelling also suggests that restrictions on the field of view that can be effectively scanned may represent an optimal trade-off between time spent detecting predators (and so not foraging) and the metabolic costs of increasing cognitive capacity.

The evolutionary and ecological history of a species helps to determine what is attended to, complicating attempts to carry out comparative experiments. A number of studies have indicated that scatter-hoarding birds depend more heavily on spatial cues such as the arrangement of landmarks than on the visual appearance of goals, whereas closely related species that do not retrieve caches of food divide their attention more equally between cues. Manipulation of cues shows that cachers

are capable of navigating using visual cues alone, suggesting that preferential use of visual cues may be due to an attentional bias rather than differential ability to learn or remember different types of cue. Attempts to compare attention in animals against human capacities may give a distorted picture, due to the prevalent use of tasks relying on the visual stimuli important to humans rather than on other modalities. Attitude

The term ‘attitude’ is commonly used to describe a person’s subjective opinion; in particular, whether they like something or not, but its true meaning is more complex. Attitude is a product of cognitive (information processing; reasoning), affective (emotional) and behavioural components. These are closely linked, so changes in one component can influence both the others and the resulting attitude. This dynamic interaction between reasoning, emotion and behaviour results in a value judgement that, together with social factors, produces what the subject believes are appropriate beliefs and behaviours.

There is a broad spectrum of attitudes towards animals. One extreme is the belief that animals are morally equal to humans, have rights and should never be used or harmed in any way (see: **Animal rights**). The opposite extreme is that animals have no intrinsic worth and can be used for any purpose, regardless of any suffering that this may cause. The beliefs of most people lie somewhere between these two extremes, often varying with the context of human–animal interactions. People variously regard animals as food, entertainment, commodities, status symbols, ‘pests’, icons, experimental tools, companions or as interesting or aesthetically pleasing beings. Perceptions of animals’ intelligence and interpretations of their behaviour – although these can often be anthropomorphic or incorrect – also play a major role in shaping attitudes. All these economic, emotional, religious, cultural and social definitions determine attitudes towards animals and how they should be treated; for example, society as a whole sanctions suffering in ‘pest’ animals that would not be tolerated for companion animals.

Regulations and codes of practice that control animal use and husbandry both reflect and are influenced by the prevailing attitudes of relevant stakeholder groups and society as a whole. Some sectors also aim to ensure appropriate attitudes by screening new staff, ensuring that workers receive **ethics** training or setting up ethics or animal care and use committees. The importance of cultivating a positive attitude towards animals is also reflected in the national curriculum in some countries, e.g. the UK, which requires that children are encouraged to empathize with animals. Audience effect

The audience effect refers to the influence that the presence or identity of conspecifics can have on the frequency, intensity or type of behaviour expressed by an animal. The feeding behaviour of domestic chickens is one well-studied example. Hens attract the attention of chicks to food with a complex behavioural display consisting of staccato calls and pecking movements directed to food on the ground. This display is not fixed. The sight of young chicks inhibits maternal feeding and prolongs the display. In natural conditions, the display of junglefowl hens is intensified when the chicks move too far away or fail to respond. Under experimental conditions, hens vocalize for longer and give more food calls when the chicks are visible but physically separated from the hen than when the chicks are free to interact with her. Nicol and Pope (1996) trained mother hens to expect that food of a particular colour was distasteful. When these hens saw their chicks eating food of the same colour, although there was no significant change in their vocalizations, other aspects of the display including food pecking, food dropping and food scratching were increased as a response to the chicks making apparent errors. Audience effects among hens are not limited to mothers and chicks: male domestic chickens give food-associated calls at higher rates in the presence of a hen than when isolated (Marler *et al.*, 1986). This occurs regardless of whether the hen is his mate or an unknown female; however, if the audience is another male chicken, the food-calling behaviour is suppressed (Marler *et al.*, 1986). Audience effects have been described in a wide variety of species, ranging from vervet monkeys (Cheney and Seyfarth, 1985) to Siamese fighting fish (Doutrelant *et al.*, 2001). (CS)

Autonomic nervous system

The autonomic nervous system (ANS) is a very complex and highly differentiated constituent of animal physiology that innervates three types of cells – smooth muscle, cardiac muscle and glandular cells – and acts as an intermediate pathway between the **central nervous system** (CNS) and the body’s organs. It regulates and coordinates many fundamental visceral functions, including gastrointestinal motility, cardiovascular reactivity, respiration, body temperature and blood pressure. It

comprises two anatomically separate systems, the **parasympathetic nervous system (PNS)** and the **sympathetic nervous system (SNS)**. (RM-F)

Autoshaping

The term 'autoshaping' was first used by experimental psychologists investigating animal learning to refer to the discovery that animals often responded to a stimulus such as a button or a lever, even though the response had never been associated with any reward. Hence, the prefix 'auto' refers to the animal's apparent shaping of the response by itself. For example, if a light is briefly illuminated a few seconds before food presentation, pigeons begin to peck the key even though no explicit response–reward contingency has been established. Since the arrival of food has been preceded by a novel event in the environment, the pigeons respond to the novel event as if it were food.

Autoshaping can be used in preliminary training to generate a reliable response which the experimenter can subsequently pair with a reward. For example, chickens will readily peck at a key introduced into their environment in an autoshaping procedure. Once the chicken reliably pecks the key, the experimenter may control the equipment so that there is a food reward after each peck. The advantage of using an autoshaping procedure rather than pairing pecks at the key with a food reward from the outset is that the former procedure is often faster in training the animal than the latter. An autoshaping procedure can also be less tedious and has the added advantage that the animal has less interaction with the experimenter than in other forms of training. (RF)

Aversion and aversives

An aversion is a reaction of avoidance. In this entry, innate aversions and conditioned aversions will be discussed with particular attention to conditioned taste aversion and the use of aversives to control the behaviour of captive animals. There are aversions that appear to be innate (instinctive or unlearned). These are responses to anything that is an extremely strong stimulus, such as a very loud sound or a very bright light. Many animals have **neophobia** – fear of anything new – and the degree to which an object is judged as new can vary, depending on the animal's boldness or lack thereof. Thunder and lightning are stimuli that most animals, including humans, find aversive. The sudden appearance of lightning and the loudness and low pitch of thunder appear to be fear provoking. This, however, is not the only reason why a dog may be afraid of thunderstorms. In addition to the initial sight and sound of an electrical storm, other frightening things may happen and be learned. For example, a tree struck by lightning may fall on the house. Many animals have an aversion to anything approaching them from above. This varies from the common complaint that a dog growls when petted on the head to a fear of hot-air balloons. Many animals are more likely to show aversions to things that startle or chase them, so a paper blowing across its path may startle a horse, and a cart dragging behind it will produce panic in an untrained horse.

All animals are averse to **pain**, but the stimuli that are associated with pain must be learned. An animal has to touch a

flame or an electric fence before it will be avoided. Because an animal must learn to avoid pain, the use of remotely activated electronic **collars** may teach the animal to avoid something other than the intended action or object. For example, if a dog is shocked when it attacks a duck on a pond, it may learn to avoid the pond rather than ducks. Pain is probably the only stimulus quality that is routinely aversive. The relationship between perceptual strength and aversion is complex.

Acute perception is not related to acute aversion. Thus, just because dogs have a very acute sense of smell, it does not mean that it is easy to repel them with an odour at a lower concentration than would be perceived by humans. Citrus odours, such as citronella, are the ones most likely to repel dogs and cats, and are used to punish barking in some bark-activated devices – the sudden spurt of compressed air from the collar may contribute to its aversiveness. Some animals seem to learn to avoid aversive things by observing others (see: **Social learning**). Anecdotal, once one cow has been shocked by an electric fence, all the other cattle will avoid it.

Taste repellents are often not very effective in the artificial control of behaviour because – although aversive or non-preferred – the aversion is only relative. A hungry cat will eat foul-smelling or bitter food, e.g. food treated with cinnamic acid. Cats and dogs given a two-choice preference test between two garbage bags of foods, one of which had been sprayed with cinnamic acid, would avoid that bag; however, in a field test, garbage bags sprayed with the repellent were torn open because that odour predicted the chicken inside. Many people spray repellents on the surfaces of fences and wooden buildings to discourage horses from wood chewing or cribbing. These probably discourage licking the surface because taste receptors are on the tongue, but there are no taste or pain receptors on the surface of the teeth. The most effective aversive agents are those that produce pain. Carbon tetrachloride, for example, stimulates trigeminal nerve receptors and will be avoided.

The use of negative reinforcement as a training method is based on aversion. Horse training is based on negative reinforcement. The horse finds being kicked in the flank aversive and quickly learns to move faster to escape. The horse learns to avoid being kicked by moving at the first touch of heel to skin. Gradually, subtler cues can be used to predict the kick. Soon, the horse will walk forward in response to the slightest squeeze of the rider's legs.

Conditioned taste aversion

The aversions to painful, bitter, loud or frightening stimuli are generally innate, although learning can strengthen them. The phenomenon of conditioned taste aversion refers to a specific form of classical conditioning associated with the development of an aversion to a given taste or smell. The unconditioned stimulus is gastrointestinal malaise. When an animal becomes ill after eating a novel food, it will avoid that food. Unlike most types of learning in which the unconditioned stimulus must be paired closely in time with the conditioned stimulus, a taste aversion can be formed when the unconditioned stimulus (nausea, vomiting) occurs hours after the conditioned stimulus of taste. Novelty is important because the animal will have learned that a more familiar food is safe, i.e. not followed by malaise.

Conditioned taste aversions were first discovered when, subsequent to irradiation, rats refused to drink flavoured water that they had drunk while being irradiated. Since then, use has been made of this phenomenon to produce a conditioned taste aversion to lamb in coyotes. Coyotes were fed lamb impregnated with lithium chloride – an emetic; after several meals that culminated in vomiting, the coyotes would not kill or eat lambs and might even vomit at the sight of a lamb. Application of this form of conditioned taste aversion has been used to reduce **predation** on sheep without killing the coyotes or interfering with their motivation to hunt other prey such as rabbits. Lamb carcasses were injected with lithium chloride and left in the sheep's home range for the coyotes to eat. One reason this method has not been more successful is that lithium chloride has a salty taste and is used as a salt substitute for people on a low-sodium diet. The coyotes were, in effect, becoming averse to salty lamb. Another problem is that coyotes may have eaten enough lamb before lithium-baited carcasses became available that lamb would not be a novel food.

Taste aversion has also been used to prevent plant poisoning in sheep and horses. Locoweed poisoning is common in many parts of the American West and South Africa. Locoweed does not produce malaise, but does contain toxins that accumulate to produce central nervous damage. For example, horses can be trained to avoid locoweed by pairing it with lithium chloride via stomach tube. (KAH)

Aversion learning

The term 'aversion learning' was first used by experimental psychologists to refer to the discovery that animals quickly and accurately learn to avoid certain stimuli. Initial work showed that when rats were made ill by independent means following ingestion of a previously preferred food, they quickly learned to avoid that food (Garcia *et al.*, 1955). Aversion learning can occur after just one trial, even if there is a long delay between the food **stimulus** and becoming ill. In this respect, aversion learning is established faster and perhaps more reliably than other conditioned responses. Aversion learning is sometimes called food aversion learning, to distinguish it from other forms of aversion learning such as colour aversion in birds learning to avoid noxious and distinctly marked prey.

Escape and avoidance conditioning are two forms of aversion learning. Escape conditioning occurs when an animal learns the response necessary to escape an aversive stimulus. Initially this is learned by trial and error and, with time, the animal quickly displays the correct response when the stimulus is presented. Avoidance conditioning occurs when an animal associates a neutral stimulus with a forthcoming presentation of an aversive stimulus. Hence if an animal is exposed to a light coming on prior to an electric shock it will, with time, learn to respond to the light in order to avoid the shock.

There are two main theories as to how aversion learning occurs: (i) the one-stage theory – the animal learns, by trial and error, to show the required response; and (ii) the two-stage

theory – the subject initially learns to associate the warning stimulus with the aversive stimulus so that the warning stimulus elicits **fear**. With time, the animal learns to escape from the warning stimulus and avoid the resulting fear.

One striking property of aversion learning is that animals learn to form some associations better than others. For example, rats are capable of learning to avoid a nausea-inducing food if it is associated with a particular taste, but not if it is associated with a sound. Conversely, they can learn to crouch to avoid a shock when it is associated with a sound, but not if it is associated with a particular taste. These constraints on learning appear to be related to the natural behaviour of the animal, since a rat may expect a novel food to cause nausea and, similarly, the sound of a predator may be likely to cause pain (which in this case was brought about by the electric shock). Hence, it appears that natural selection has honed the animal's readiness to form certain associations.

One application of aversion learning techniques may be to train animals to avoid certain foods. For example, Pfister (2000) trained cattle to avoid eating a target plant (green pine needles) by making them ill through a lithium chloride injection subsequent to ingestion. Once released, cattle that were made ill following ingestion initially avoided the target plant more than controls. However, 16 days after release, trained and control cattle were eating similar amounts of pine needles. He found that trained cattle did not avoid pine litter initially (i.e. pine needles on the ground), and this failure of cattle to generalize to other forms of pine needles may have led to them losing their aversion to pine needles. One possibility is that if an animal accidentally ate the target plant while eating pine litter, and did not become ill, then the aversion conditioning would be weakened till eventually it would disappear. None the less, refinement in the training procedure should be possible to eliminate the rapid loss in aversion, and may yet prove to be a valuable method in the management of consumption of poisonous plants by livestock.

Aversion learning has also attracted attention from animal welfare scientists investigating the issue of animal suffering. From our own experience it could be argued that one function of **suffering** is to learn to avoid or generally try to escape from certain situations. It could also be argued from our own experiences that the greater the suffering then the greater our attempts to avoid situations that induce such feelings. Therefore by measuring the extent to which animals avoid certain situations, it may be possible to rank how much suffering is caused by each. For example, Rushen (1996) studied learning to avoid certain handling procedures in sheep by training them to run along a race to reach an area where the procedure was carried out. He measured the latency to run along the race in seven trials and assumed that longer latencies would indicate greater aversiveness. Using such an approach, he was able to rank the relative aversiveness of various handling procedures.

In some respects, an aversion learning technique is more useful than traditional behavioural measures of **welfare**, because the animal's immediate behaviour may be influenced by a large array of factors, not just the imminent handling procedure, making results difficult to replicate and interpret. Additionally, changes in physiological **stress** would probably not provide a good comparison of various handling procedures, as the stress response is seldom accurately related to the

intensity of the **stressor**. In contrast, aversion learning techniques are sensitive to small variations in the intensity of stimuli, such as electric shock, noise and vibration.

However, aversion learning techniques are often not reliable. First, the natural response of the animal may interfere with the performance of the measurable avoidance behaviour. For example, chickens cannot be trained to move away from a predator-type stimulus because the natural response in this species is to freeze. Secondly, learning and **memory** ability tend to differ considerably, not only between animals of related species but also between individuals of the same species. Hence, negative results may easily arise because of problems with the method rather than from a lack of aversiveness of the treatment. The use of aversion learning techniques therefore requires an understanding of the memory and learning ability as well as a detailed knowledge of the behaviour of the species.

Avoidance behaviour

Avoidance behaviour can be described as a sequence of actions involving retreat from, or lack of approach to, a perceived threat **stimulus**. For the purpose of scientific study, avoidance behaviour can be sub-divided into two main categories: unconditioned (unlearned) and conditioned (learned).

Unconditioned avoidance behaviour

Unconditioned behaviour is assumed to be entirely instinctive. In the parlance of **ethology** – the study of animals' natural action patterns (see: **Tinbergen, Niko; Lorenz, Konrad; von Frisch, Karl**) – unconditioned behaviours are those that are 'released' by 'triggers' or 'cues'. From a developmental point of view, it is impossible to rule out some form of learning, since from inception the organism is constantly being stimulated by the environment and so may react on levels as fundamental as the genome. The main point is that fixed-action patterns emerge as a function of the organism's particular structure and, having done so, appear to remain stable and resistant to change. By contrast, learned behaviour is more malleable and can change in response to environmental pressures. So learned behaviour is adaptive, whereas unlearned behaviour can be described as pre-adaptive.

The cockroach's (e.g. *Periplaneta americana*) aversion to light is a common example of unconditioned avoidance behaviour and clearly serves as a survival strategy. In the dark, the cockroach is less vulnerable to predation. So strong is its drive to seek darkness that it will run towards a dark escape hole in the wall even if a bright light exists directly over the hole. This is a good example of the non-malleability of uncon-

ditioned avoidance behaviour. Predator odours serve as another example. Cats are well-known predators of rats and mice. If a laboratory rat (e.g. *Rattus norvegicus*) is placed for the first time in an apparatus that has a worn cat collar attached at one end and a hide box at the other, it will perform a characteristic posture known as 'head out behaviour' (Dielenberg and McGregor, 2001). Descriptively, this involves the rat poking its head out of the hide box entrance hole while vigilantly orienting itself towards the cat collar. It performs this behaviour despite having never experienced a cat before, either directly or indirectly through its littermates. It also shows more generalized avoidance behaviour in that if it is exposed repeatedly to the cat collar, it will decrease its vigilant behaviour, but will not increase its approach to the collar. Interestingly, it will perform occasional forays up to the collar to investigate it. This is known as 'risk assessment', and is an important component of avoidance behaviour in that it allows the animal to determine the degree of risk that a threat stimulus holds.

Conditioned avoidance behaviour

Conditioned avoidance behaviours involve learning something aversive about a stimulus that is either intrinsically threatening to the species or has acquired some threatening aspect due to an association with an intrinsically threatening object or process.

Pavlov's famous experiments with dogs demonstrate the process of conditioning (see: **Conditioning**). Conditioned stimuli rely on being contextually associated with unconditioned responses. Unconditioned responses, in turn, are strongly linked to survival.

To condition an animal to avoid a place or an object, the experimenter must associate a conditioned stimulus with something the animal intrinsically fears (as opposed to food, which the animal likes). A classic example is the shuttle box experiment. The rat is placed in the apparatus, a box with two compartments, then occasionally given a mild foot shock irrespective of which compartment it is in. Importantly, just before delivering the shock, a tone is sounded. The animal quickly learns that when it hears the tone, it needs to get out of the compartment it is in. Soon the animal can be made to shuttle back and forth at the sound of the tone alone. In this way, a conditioned avoidance can be established. The animal has been conditioned to avoid the compartment in which it hears a tone.

A more subtle example has been shown in the case of rhesus monkeys (*Macaca mulatta*). Mineka and Cook (1988) demonstrated that juvenile rhesus monkeys learned to be fearful of snakes by watching video recordings of adults responding fearfully towards snakes. From this experiment, some researchers concluded that rhesus monkeys are not born with an innate fear of snakes; rather, they are born with a preparedness to fear snakes, which can be awakened given the appropriate social and/or environmental cues (NB: this is a contentious hypothesis). Certainly, it makes evolutionary sense, since failure to learn fear about a truly dangerous stimulus could mean the difference between life and death. Interestingly, when the same monkeys were shown videos of adults responding fearfully to flowers (the adults were conditioned to fear the flowers), the juvenile monkeys did not form a response as strong as was observed with snakes. The

reason for the weaker conditioned avoidance response is perhaps best explained by the fact that flowers do not normally present a survival threat to the monkey.

Another important phenomenon found with conditioned avoidance is the process of ‘**extinction**’. Fear reactions to intrinsically non-threatening objects can fade over time. For example, this occurs when an intrinsically non-threatening object, which was once paired with **pain**, is repeatedly exposed to the animal without pain. Gradually, the animal will learn that the stimulus is non-noxious. This is especially the case when the animal has been deprived of food and the non-threatening stimulus is a palatable food. The same process does not occur with a true threat stimulus, and once again reinforces the notion that each species possesses a predisposed fear towards certain threat objects relevant to its survival. (RoD)

Awareness

The use of the term ‘awareness’ can roughly be categorized into three instances: (i) as a synonym of **consciousness**; (ii) as a subjective state that is in some way differentiated from consciousness (perhaps being more ‘basic’ or elemental, or one of a number of ‘types’ of consciousness); or (iii) defined in purely neurological, behavioural or cognitive terms that do not necessarily imply the presence of any subjective element.

Awareness as a synonym of consciousness

Awareness is commonly used as one of a series of rough synonyms (Block, 1995), together with consciousness, **sentience** and so on, which point towards the elusive phenomena of private, **subjective experience**: what it is like to be either ourselves or another animal (after Nagel, 1974). Since many believe consciousness cannot be defined in a way that is non-circular, it is not surprising that definitions of one commonly cite the other in this manner. To say that an animal has awareness in this sense is to talk of a state that is arguably outside the limits of scientific measurement or proof, but is central to considerations of animal **welfare** and legislation.

Awareness as a type of consciousness

Griffin (1976) notes that as a means of describing animals’ mental experiences, some find awareness more acceptable (i.e. less controversial) than consciousness. But how might awareness differ from consciousness? Some use the term to refer to a particular ‘type’ of consciousness (see also the section below for other ways in which the term is used). Examples of this in the scientific and philosophical literature are manifold, and sometimes contradictory, demonstrating that such semantics are very much in the mind of the beholder.

Lambie and Marcel (2002), for example, distinguish two levels of consciousness: phenomenology (which is ‘what it is

like’ to have particular experiences, such as the sensation of pain, seeing a certain shade of green and so on) and awareness (which is ‘a kind of knowing’ about that phenomenology). The difference between these two levels of consciousness can be illustrated by asking the following question: ‘How does your left foot feel?’ Before being asked that question, did the feeling in your left foot exist? Unless you were aware of your left foot beforehand (e.g. maybe you were aware your new shoes were starting to pinch your left foot, or perhaps someone has just trodden on your toe and you were aware of the pain), it is likely that information (i.e. how your left foot feels) only became accessible to verbal report once you had been asked about it.

However, the feeling may, in some sense, have existed before then, i.e. phenomenology might occur separately from awareness. They note that the philosopher Block (1995) divides these mental phenomena along very similar lines, also distinguishing two types of consciousness: phenomenal consciousness (or P-consciousness, for short) and access-consciousness (A-consciousness). Block states that P-consciousness cannot be defined non-circularly, other than saying it is ‘what it is like’ to be in a particular experiential state (e.g. having sensations, feelings, perceptions, thoughts, desires, emotions and so on), and distinguishes this from A-consciousness, which is marked by ‘the availability for use in reasoning and rationally guiding speech and action’. In contrast to Lambie and Marcel, though, he feels more comfortable equating P-consciousness with being aware and A-consciousness with being conscious (i.e. tends to label these phenomena the other way round; **see also: Attention**).

Awareness without (necessarily any) consciousness

The term awareness can be used without necessarily implying the presence of any subjective experience. Chalmers (1996) provides a good working definition of awareness in this context: ‘Awareness can be broadly analyzed as a state wherein we have access to some information, and can use that information in the control of behaviour. One can be aware of an object in the environment, of a state of one’s body, or of one’s mental state, among other things.’

A definition such as this, expressed in terms of information processing and behavioural control, can be used to infer the status of an animal’s *awareness* by observing particular stimuli and behavioural output, while remaining agnostic (i.e. non-committal) with regard to the existence of any private, subjective experiences. For example, an observer might state that an animal has become aware of a nearby predator by noting an acute, obvious change in behaviour (e.g. fleeing in the opposite direction) that is informed by, and an adaptive reaction to, the presence of that predator, without necessarily inferring the presence of any accompanying subjective element.

Of course, the lack of any apparent behavioural change does not necessarily mean an animal is unaware of a particular stimulus: in the above example, the animal may have been aware of the predator’s approach but chose to stay still, or was unable to engage in an active behavioural response due to injury or illness. In keeping with this type of definition, Jennings (1998) defines awareness as the physical (neurological) processes associated with consciousness in those who are capable of such subjective experience, but suggests an animal might be aware without being conscious, i.e. an animal might

undergo physical, neurobiological changes, indicating a change in the informational state of the brain, while essentially being an automaton, incapable of any subjective experience.

Chalmers' view of awareness is perhaps one of the most carefully considered and complete. Following his working definition, quoted above, he proceeds to define awareness as the 'psychological correlate of consciousness': the cognitive processes associated with the phenomenal, subjective property of the mind (see also: **Cognition; Mentation**). Consciousness does not occur without awareness, but he does not regard them as synonymous: the former refers to how the mind feels and the latter to what it (causally and functionally) does.

Whether awareness can occur without consciousness, though (as Jennings' definition allows), is a little more complex: Chalmers notes that he can be in some sense aware of a given fact – for example, the US President's identity – but there is a distinction between this fact being in his memory, accessible on request but not presently retrieved, and it actually being directly accessed so that he experiences it. As a result of these nuances, Chalmers defines awareness as requiring *direct access* (i.e. he defines it as a more faithful psychological correlate of consciousness), and he allows for the possibility of awareness occurring in non-linguistic species by characterizing the contents of awareness as being available for use in the global control of behavioural processes (rather than stating that the contents of awareness are solely characterized by their availability for verbal report). Although Chalmers' treatment of the term will not satisfy everyone's understanding of awareness, it is none the less an interesting example of how defining awareness in a cognitive sense can allow it to be variously decoupled and linked to subjective experience.

The content of awareness

Almost regardless of which of the above definitions one has in mind when talking about awareness, what an animal is aware of will depend on the type of information that is accessible and available. This will differ between individuals and across species due to differences in cognitive capabilities and the limitations of sensory apparatus (see also: **Perception**). For example, olfactory awareness may be greater in an animal whose olfactory sense is particularly rich and well developed. Such an individual may be aware of differences in odour that another might be unable to distinguish, or become aware of the presence of an odour when it is at a much lower concen-

tration in the air. Similarly, rats' hearing typically extends into the ultrasound range, i.e. to frequencies higher than those an (unaided) human can detect. Therefore, a rat kept in a laboratory, for example, might be aware of sounds to which a human is oblivious, possibly to the detriment of its welfare or to the detriment of experiments in which the rat is a subject.

In addition, Kendrick (1997) notes that the '**motivational state**' of an animal might be an important determinant of what information reaches awareness, a conclusion he draws from experiments indicating that when a ewe is not sexually receptive, she shows very little neurophysiological change when presented with the image of a ram; however, when she is in oestrus, she exhibits a substantial neurophysiological response (see also: **Motivation**).

Finally, the cognitive capabilities of an individual or species will be an important determinant of what one is, or ever can be, aware of. Although some animals are capable of forming simple abstract concepts, only humans are likely to be aware of highly abstract ideas (e.g. globalization, quantum mechanics, etc.); similarly, there are likely to be differences between individuals and species in the extent to which an animal can be aware of the state of another's mind, or be aware of aspects of 'self' (see also: **Concept formation; Self-awareness and self-recognition; Self-consciousness; Theory of mind**).

Backtest

According to Hessing *et al.* (1993), a piglet's **coping** style can be obtained during the suckling period by assessing its response during a behavioural test, known as the 'backtest'.

Coping style is a concept in which **stress** responses shown by individuals within the same species may be divided into distinct categories. It is based on behavioural, physiological and psychological responses that are consistent across time and across situations, even if their overall level changes. Two distinct coping styles, 'active' and 'passive', have been shown to exist in rodents. Active individuals are characterized by high levels of **aggression**, greater activity levels and other physiological and neuroendocrinological characteristics predominant of a fight/flight response. On the other hand, passive individuals display the opposite pattern by showing conservation/withdrawal responses. A strong individual differentiation that might reflect different coping styles is present in several species (see Koolhaas *et al.*, 1999 for a review), but it is controversial in pigs.

In order to investigate the existence of coping styles in pigs, Hessing *et al.* (1993) introduced the backtest. Since its creation, the backtest has been widely used and there are slight variations as to how it is conducted. In general, a piglet is removed from its home pen, then placed on a flat surface (i.e. table) where it is manually restrained in the supine position for 1 min. To restrain a piglet, the handler places the palm of the left hand firmly over the piglet's head, and keeps its front legs between his/her fingers. The handler's right hand is placed loosely over the piglet's hind legs. Piglets' behavioural responses during the backtest range from uninterrupted immobility to continuous struggling, and show a unimodal distribution. The number of escape attempts, usually defined as a bout of wriggling, is used to assign a 'backtest score' to each piglet. Piglets that perform a low number of escape attempts are considered 'low resistant' (LR), whereas those that perform a high number of escape attempts are considered 'high resistant' (HR). The criteria used in defining the backtest score have varied among different investigators since the original description of the backtest. Nevertheless, it has been suggested that the backtest score can be predictive of piglets' responses to other stressful situations, and can consequently be used as an indicator of coping styles in piglets.

Several factors contribute to the popularity of the backtest among some researchers. The backtest is a quick and inexpensive way potentially to assess piglets' coping styles. It allows us to better understand the genetic influences on piglets' coping style, as individuals are young, naive and unlikely to be affected by previous experiences. The main argument for using the backtest as a measurement of piglets' coping style is that several studies have demonstrated that backtest scores correlate with piglets' responses in social and non-social tests, as well as with physiological measurements indicative of distinctive coping styles. For instance, animals classified as HR in the backtest have been shown to have a stronger fight/flight response pattern by being more aggressive in social tests, exploring a novel environment less, having lower cortisol levels and higher mean **heart rate**, **blood pressure** and metabolism than LR piglets, as would be expected for an 'active' individual. LR and HR also differ in apomorphine susceptibility, immune reactivity, post-mortem heart muscle alteration and stomach wall damage.

Despite its potential benefits, the backtest has been widely criticized. One of the main criticisms relates to its methodology, especially with regard to categorization of individuals based on the backtest score. Most studies that report the existence of distinct coping styles in pigs use only the extremes of the population when classifying individuals as HR or LR. This exclusion of any intermediate group results in the erroneous analysis of a unimodal distribution as a bimodal distribution. In other cases, the entire population is arbitrarily divided into two groups. It is generally accepted that domesticated pigs demonstrate large individual variation, but attempts to categorize animals on distinct coping style, as done for rodents, have been less successful and show conflicting results.

Other problems have been reported with the utilization of the backtest. Although some researchers find a correlation between the backtest and other behavioural and physiological measures, these results cannot always be replicated. One possible explanation is the lack of intra-test consistency for the backtest. Also, it is not clear at this time what are the appropriate behavioural tests or physiological measurements necessary to find correlations in order to define an individual's coping style. The lack of theoretical background makes the backtest difficult to interpret and evaluate.

There are several possible explanations for the discrepancy in the results reported by studies in pigs and why the patterns in other species, such as rodents, may not apply to domesticated animals.

Domestication may play a role in the distribution of individual characteristics. Genetic selection of pigs that are more adapted to farm conditions may indirectly result in the selection for one type of coping style and a consequent reduction in individual variation. Another explanation is that wild ancestors of the domestic pig, unlike rodents, did not undergo selective pressures to evolve two distinct coping styles. At this time, the data on the existence of distinct coping style in pigs and the validity of the backtest are conflicting and inconclusive. Methods for assessing coping style, such as the backtest, need to be critically evaluated before being used routinely.

Baiting

Baiting is when an animal(s) is set on another animal, usually a wild animal. In the past this has included bears, bulls and badgers, but baiting of all these species is now illegal. As the animal that is baited is

often stronger than the animals used to bait, the baited animal is handicapped in some way through being tethered or chained (bears), through fracturing a limb or jaw (badgers) or through being confined in a space from which it cannot escape. Most commonly dogs are used to bait, the traditional breeds being terriers (badgers) and bulldogs (bulls) or other, larger, dogs. These traditional countryside 'sports' were banned in the UK (e.g. Protection of Badgers Act 1992) but are still not uncommon in other countries.

(DBM)

Bar biting

Bar biting is regarded as a stereotypic behaviour (**see: Stereotypies**) in which the animal carries out repetitive mouthing and biting of the metal bars of its environmental enclosure. It is commonly seen in rodents, calves and pigs housed in barren, confined environments and with restricted access to food. However, it has also been implicated as having a function in buffering gastric acidity in sows.

Beak trimming

The beaks of laying hens are commonly trimmed in the first 10 days of life. Trimming involves the removal of up to one-third of the upper and lower beaks. This is done by various means, the commonest being a hot, cauterizing blade. Beak trimming reduces feather loss and **cannibalism**-associated injury or deaths. It is considered of particular benefit in noncage-housed flocks, where outbreaks of cannibalism can spread rapidly. There are other economic advantages to the procedure: trimmed birds tend to waste less food and have increased food conversion. The relative benefits of beak trimming vary among genetic stocks of birds.

There is evidence that the procedure is likely to be acutely painful, as the beak has many nociceptors. A reduction in feed pecking after trimming can be eliminated by the application of topical analgesia to the beak stump at trimming. There is anatomical evidence of neuroma formation following beak trimming in older pullets. There is also electrophysiological evidence of abnormal neural discharges, implicated in chronic **pain** syndromes, recorded from stumps up to 83 days after trimming. There is no evidence of neuroma formation in **turkeys**. Neuromas are less likely if layer pullets are conservatively trimmed at hatch. Behavioural evidence consistent with pain, including decreased pecking rates, has been seen in **chickens** and turkeys for several weeks after trimming. Behavioural changes were less long-lasting in chicks that were trimmed at 1 day of age when compared with those trimmed at an older age. The dermis of the beak normally contains many sensitive mechanoreceptors capable of fine tactile discrimination. These are absent from the scar tissue left after trimming, and this may account for some of the long-lasting behavioural changes seen. The procedure is frequently regarded as a **mutilation** and some governments discourage its routine use as a prophylaxis against cannibalism.

Bear

The bear family, Ursidae, in the Order Carnivora, is comprised of only eight living species, which range from the Arctic to the tropics. All but the polar bear are primarily forest dwellers, but they also inhabit grasslands, arid shrublands, tundra and semidesert. Bears once existed on all continents except Australia and Antarctica, but prehistoric extinctions of several species, range collapse from habitat loss and over-hunting have resulted in their extirpation from Africa, most of the Middle East and Western Europe, Central America and all but the northern Andes of South America.

Descended from carnivorous canid ancestors, modern bears are mainly omnivorous. The polar bear, the most recently evolved species, is the only obligate carnivore, subsisting almost entirely on seals. Conversely, giant pandas, strict herbivores, subsist almost entirely on bamboo. Sloth bears, of the Indian subcontinent, are ant and termite specialists. All other bear species are known to eat insects, as well as numerous kinds of fruits and other plant matter. Sizes of bears (ranging from 30 to over 600 kg), reproductive rates, life history patterns, behaviour and social organization correspond largely with food supplies that vary geographically, seasonally and from year to year.

Three species of bears (brown, American black and Asiatic black) that occupy northern temperate environments hibernate when food supplies disappear during winter; they must then rely solely on stored body fat. In some parts of their geographic ranges, where food is available year-round, they may remain active. Debate still exists as to whether bears truly hibernate, as their body temperature drops only slightly; however, their heart rate and respirations profoundly decline, and they can endure periods of up to 7 months without eating, drinking, urinating or defecating, a feat matched by only a few species of ground squirrels (considered true hibernators).

Northern hemisphere bears (except pandas) give birth while hibernating. Thus, hibernating mothers must not only survive without nourishment, but also must provide nourishment

P.49

(milk) to newborn young for up to 3 months before emerging from their dens and eating again. In non-hibernating species, females are also restricted to a den site before and after birthing, and may not eat for weeks or months, suggesting that they too possess an adaptation akin to hibernation.

Average litter sizes range from one to three cubs, varying by species and area; some individuals produce litters of four to six (rarely). Average age of first birthing ranges from 3 to 10 years, again varying between species and populations; in areas with abundant food (natural or human-related), bears grow faster and mature earlier.

Once mature, bears generally give birth every 2 or 3 years, although the inter-birth period is extended by 1 year or more in some brown bear populations. Females become reproductively senescent in their mid-to late 20s, but may live into their early to mid-30s.

Cubs are typically cared for by their mother until she mates again. However, mothers nurse cubs for only about 9 months - up to the first winter in temperate populations (but may resume lactation after hibernation in some cases). First year cub survival averages 60-75%, but varies widely.

In the few instances where family break-up has been witnessed in the wild, females actively drove off their cubs after males began to show interest in mating. It is possible that males are also actively involved in family break-up in some circumstances.

Mating occurs several (up to 8) months before birthing, although the fertilized egg does not implant in the uterus until 2 months prior to parturition. The period of delayed implantation may enable bears in poor bodily condition to easily abort a pregnancy. However, observations of captive pregnant bears in poor condition indicate that they are more apt to give birth and then immediately consume their young. Only the tropical sun bear appears not to have a distinct mating and birthing season.

Males mate with several (often three or more) females during a single breeding season, and females mate with multiple males. All mature females breed, whereas male breeding success is related to dominance status. Males are often at least 50% larger than females. Dominance among males is related to their size and age, and is established through both subtle and **agonistic** interactions, sometimes resulting in facial wounds and broken teeth.

Males may sequester females for mating and mate repeatedly for 1 or more days, possibly to stimulate ovulation. Breeding with multiple males sometimes results in litters of mixed paternity, as evidenced by genetic analysis. However, in species where coat colour varies from black to various shades of brown, litters of mixed colours do not necessarily signify mixed paternity.

Aside from mating and cub rearing, bears are generally solitary, although not asocial. They may congregate peaceably at concentrated food sources, such as rich berry patches, fruiting trees, salmon streams, insect aggregations or human-related areas such as garbage or agricultural fields. They also regularly communicate with each other through scent and physical marking of their environment (e.g. biting and rubbing on trees), occasional encounters and subtle **vocalizations**. Home ranges between and within sexes normally overlap, although this varies with food abundance. Home range size, which varies by four orders of magnitude across species and up to two orders of magnitude within species, is also related largely to food availability. Bears may make extensive seasonal movements, laterally or altitudinally, to locate better sources of food. Four of the eight species span an altitudinal range of more than 3500 m, and some individuals range over more than 1000 m of elevation.

Bears have few natural predators. Adult males may kill cubs, and fights between adult bears (e.g. females protecting their cubs from males) may result in death. In Asia, tigers and leopards are potential predators, although bears are generally adept and aggressive enough to chase them away. Sloth bear mothers carry their cubs on their backs, possibly as a defence against tiger **predation**. Young bears of most species climb trees as a refuge from predators. Andean bears of South America and sun bears of South-east Asia appear to be the most arboreal, but this behaviour is related more to their foods than threats of predation.

Humans are the main source of bear mortality. Four species are legally hunted in parts of their range. Most legally hunted populations are presently increasing, because **hunting** is limited and well enforced. Illegal hunting and habitat loss pose much greater risks, particularly in parts of Asia where deforestation and poaching of bears for their gall bladders are causing populations to fragment and decline.

The bile (found in the gall bladder) of bears contains unique compounds that may be instrumental in the hibernation process. Long ago, people in Eastern Asia discovered medicinal properties of these compounds, making bear bile a valuable commodity - this is problematic in today's world where humans are more plentiful and bears more rare. To supply this demand, thousands of bears in China and Vietnam are raised on farms so their bile can be regularly drained with a catheter inserted into the gall bladder. International animal welfare groups are working to rectify this situation.

Conservationists focus on reducing habitat loss, poaching and the removal of wild young bears for **pets**. Only two bear species, American black bears and brown bears, are not considered globally threatened (but many small, isolated brown bear populations are).

Behavioural ecology

Behavioural ecology is the study of animal behaviour within its evolutionary and ecological context - the integrative study of behaviour across **Tinbergen's four questions**, which address the **ultimate** and **proximate** causation of animal behaviour. Behavioural ecology thus integrates the evolutionary focus of traditionally field-based **ethology** with the methodological rigour of laboratory-based **comparative psychology**.

As an evolutionary science, behavioural ecology addresses the consequences of behaviour for an individual's evolutionary **fitness**. That is, how does the expression of the behaviour alter the likelihood that the individual's genes are replicated in future generations, compared with the replication of genes of individuals exhibiting other behaviours? The relative replication of an individual's genes in future generations through the individual's direct descendants is that individual's direct fitness, which is determined by the process of direct selection. Because an individual's genes are also present via shared co-ancestry in collateral kin (e.g. siblings, cousins), an individual's genes are also replicated in future generations in the descendants of collateral kin (e.g. nieces and nephews), although at a lower per capita efficiency than in direct descendants. The relative number of additional copies of genes in collateral kin is an individual's indirect fitness, and the process that determines an individual's indirect fitness is called kin selection. The sum of an individual's direct and indirect fitness is its inclusive fitness, the parameter altered by natural selection.

One of the great puzzles in behavioural ecology has been the existence of behaviours that appear altruistic. **Altruism** is the general term for behaviours that an individual performs at some cost to itself, to the benefit of another. Because of the cost of altruism, these behaviours appear to counter predictions from natural selection. The recognition that indirect fitness mattered during natural selection was a key advance in understanding the evolution of behaviours that otherwise appeared altruistic. That is, natural selection could result in the spread of an apparently altruistic behaviour if the individual performing the

behaviour sufficiently increased its own inclusive fitness by helping kin. Under current understanding of behavioural evolution, altruism among non-kin is likely to evolve only under specific conditions, such as through a reiterated process of reciprocal altruism.

Because the indirect fitness benefits of behaviour are dependent on the kinship between individuals, natural selection has shaped mechanisms that produce discrimination of kin from non-kin, and those mechanisms can have an impact on management of captive and domestic populations, as well as conservation efforts. For example, the cues used by prairie falcons (a relatively abundant North American raptor) to identify and feed their own nestlings are sufficiently vague that these falcons will rear young peregrine falcons (an endangered raptor) placed into their nest, in a process called crossfostering (**see also: Adoption**). If natural selection had resulted in the use of very precise cues by prairie falcons, cross-fostering would not have been an option for those seeking to rebuild peregrine falcon populations.

The discrimination of kin from non-kin has ramifications beyond altruistic behaviour. Inbreeding can have severe fitness consequences for an individual, and natural selection has shaped mechanisms of mate choice to reduce the risk of inbreeding. Possible cues of kin discrimination during mate choice include olfactory or other phenotypic cues, as well as learned associative cues. For example, striped mice avoid inbreeding by familiarity through prior association. The likelihood of successfully breeding striped mice, and other species that use familiarity as a cue to avoid inbreeding, would be increased by housing them separately during development.

Sexual selection is another topic in behavioural ecology that has applied implications. Sexual selection is the special case of natural selection that increases the likelihood of behaviours that improve reproductive success, at the cost of survival. In general, female reproduction is limited by access to resources, and male reproduction is limited by access to females. Sexual selection thus imposes selective pressures on males to compete for access to females. In rhinoceroses, male competition for females is based on size and aggression, so multiple male rhinoceroses cannot be kept in the same captive enclosures even with sufficient food and water.

Whether or not multiple individuals can be housed together may be influenced by aspects of a species' behavioural ecology other than its mating system. For example, the social units of wild spotted hyenas sometimes include over 100 individuals. However, **agonistic** encounters (i.e. win-lose encounters) in spotted hyenas are often resolved when the loser of an encounter temporarily leaves the vicinity of the winner. In captivity, a huge amount of space would be required for an individual hyena to separate itself from others; in the absence of enough room for spatial conflict resolution, aggression levels among captive hyenas rise to dangerous levels, so in practice these otherwise social animals cannot be kept in social groups. In contrast, many social birds such as monk parrots fare better when housed in groups; understanding a species' social behaviour can improve captive management plans.

Another aspect of an animal's behavioural ecology with clear applied consequences is the organism's mating system, which influences the amount of genetic diversity present in a population. An estimation of the number of individuals living in an area does not necessarily reflect the genetic diversity among those individuals, which represents the capacity of the population to respond to current and future evolutionary pressures. If sexual reproduction is highly skewed, as in polygamous mating systems where one male sires most of the offspring, then the existing genetic diversity in the population will be lower than if reproductive success were more evenly distributed, as in a monogamous mating system. In addition, **inbreeding** can accumulate more rapidly in mating systems with high reproductive skew, and an accumulation of inbreeding can reduce survival and reproductive success.

Behavioural ecology can also shed light on the impact of species interactions in contexts that have not previously existed. As an example, although the foraging behaviour of predators and the anti-predator behaviour of **prey** co-evolve in an 'evolutionary arms race', human activities may alter predator abundance in ways that have cascading impacts on prey. Predators have typically evolved to hunt more

than one species, and have evolved under conditions in which they rarely face a superabundance of food. Consequently, some well-fed predators continue to hunt in response to cues from prey. **Predation** rates by individual feral and commensal cats

P.51

are not tightly linked to the amount of food they receive from humans; although the demographic consequences of predation on prey populations are not always clear, subsidized predation by domestic cats often appears to outstrip the growth rate of small bird and mammal populations.

Behavioural elasticity

This is a term taken from economics referring to the behavioural effect of altering an animal's income (e.g. energy budget) or the cost of performing the behaviour. High elasticity means that small increases in cost, or decreases in income, cause large decreases in performance of the behaviour. Less valued behaviour may show higher elasticity. Conversely, inelastic behaviour is observed when consumption is maintained as price increases (or income decreases) and is indicative of more valued behaviour.

(HJW)

Behavioural need

A need is a requirement for something that is essential or very important. At any moment an individual has a variety of needs, some of greater urgency than others. The principle of a behavioural need is that *performance* of that behaviour is essential for psychological well-being. Thus, if performance is prevented, the animal may experience frustration and ultimately suffering. The phrase was first coined in a paper presented by W.H. Thorpe to the Brambell Committee in 1965, where he suggested that animals possess behavioural needs apart from the more obvious physiological needs. The phrase became popular and is still a key concept in discussions of animal welfare.

Animals generally have a complex and varied behavioural repertoire and it is unlikely that, in any given captive or managed environment, they need to perform all the behaviours in their repertoire. For example, it may not be beneficial for animals to show anti-predator behaviour in the absence of a predator. Providing predatory cues to produce the behaviour could cause stress to the animal. It is therefore essential that we consider which behaviours are important for captive animals to perform.

It is important to distinguish between ultimate and proximate needs. Dawkins (1983) described ultimate needs as being those that are necessary for life, such as food and water. There is an obvious daily need for animals to feed and drink, as denial of these would result in reproductive failure and ultimately death.

So all animals have ultimate needs that must be met, but they may also have proximate needs. Failure to perform a behaviour that meets a proximate need may have less catastrophic or immediate consequences, but there may still be welfare implications, particularly if proximate needs are not met over an extended period of time. For example, a captive tiger may be highly motivated to perform hunting behaviour even when food is provided. Failure to hunt will not result in **death**; however, it could negatively impact on that animal's **welfare** through increased stress levels.

In the wild, ultimate and proximate needs will generally occur together. In the example above, a tiger will experience a proximate need for food, resulting in a motivation to hunt which will meet the ultimate need of avoiding starvation. In captivity, however, ultimate and proximate needs may become separated, making it difficult to determine which behaviours are actually needs. It is simple to understand why animals' ultimate needs must be met, but there is no easy way to tell whether, for example, a tiger needs to hunt, a chicken needs to dust bathe or a pig needs to forage. Therefore the underlying **motivation**, and consequences of prevention, of each behaviour must be thoroughly investigated.

Why might it be important to consider behavioural needs?

The idea of some behaviours being important to animals is embedded in several national and international Animal Welfare Codes, which state that animals have a need to express most normal patterns of behaviour. Yet the commercial conditions in which we keep farm and **laboratory animals** often deprive them of resources that they could naturally access. For instance they may have reduced or no access to mates, a lack of space, an inability to create social distance, limited foraging possibilities or no control over their environment. This means that they are being prevented from performing a number of their normal behaviour patterns.

For some behaviours the issue is quite straightforward, in that the conditions in which the animals are being kept do not enable them to meet their behavioural needs. For example, in the period prior to farrowing, sows have been shown to be highly motivated to perform nest-building behaviours. When they are kept in **farrowing crates** without any bedding they are restricted in their movements and have no means of performing this behaviour. This constraint results in increased **hypothalamic-pituitary-adrenal axis** activation, which is indicative of higher **stress** levels, and sows may also suffer higher levels of stillbirth. Thus it seems clear that sows have a behavioural need to perform nest-building behaviour prior to farrowing.

For other behaviours the issues are more complicated, since the behaviours that the animal is being prevented from performing would normally be carried out in order to obtain resources that are being readily supplied for them. For example, in the wild many animals would spend a large proportion of time foraging, and for pigs this may be around 50% of their time budget. Even though they may not be able to forage in the same way in commercial or laboratory conditions, concentrated high-energy food is in ready supply. This gives two possibilities, one being that the animals do not 'need' to perform foraging behaviour, they simply need to satisfy their energy and nutrient requirements and, since sufficient food is provided to meet these requirements, the animal will have no remaining motivation to forage. Thus, restricting the opportunity to forage will not reduce welfare. However, it is also possible that animals have a behavioural 'need' to perform foraging behaviour, whether or not food is freely available. Foraging behaviour may, for example, be motivated at an appetitive stage. Thus, an animal may desire to search or

P.52

explore possible feeding sites prior to feeding. In this case the actual performance of foraging behaviour is important to the animal, as well as the outcome of the behaviour, i.e. the detection or consumption of food. These same principles can be applied to many other behaviours that animals kept in commercial or laboratory conditions are not able to perform.

Evidence for behavioural needs

The idea that animals have behavioural needs is intuitively appealing; however, it is important to consider the evidence. Sherwin *et al.* (2004) examined burrowing behaviour in laboratory mice. A comparison was made between the time mice spent nesting or burrowing when provided with a compartment containing peat and the same measure when they were supplied with previously constructed burrows. The mice spent an equal amount of time constructing new burrows in the presence of previously constructed ones as when no burrow was present. This suggests that mice need to perform burrowing behaviour as opposed to simply requiring a ready-formed burrow. An argument used against such evidence for behavioural needs is that the resource that is provided may be deficient in some way, and this is why the animal continues to show the behaviour. However, Sherwin's study ensured that the burrows had been dug by the same individual in a previous stage of the experiment. It is therefore difficult to argue that the burrows provided were in any way unsuitable for the mice.

If an animal has a need to perform a behaviour, then keeping it in conditions where it is unable to do so may result in **frustration** and reduced welfare. It is therefore important to distinguish which behaviours are needs.

Motivational aspects of behavioural needs

Some suggestions have been made as to the characteristics of behaviours that are likely to be needs. First, it has been proposed that the behavioural needs will be most likely when a candidate behaviour is primarily motivated by internal causal factors, e.g. changing hormone levels. This is logical, since a behaviour that has external causal factors would be triggered only in certain environments, whereas an internally motivated behaviour may be triggered in any conditions. For example, if the primary external causal factor for rooting behaviour in pigs was the presence of a suitable rooting material, then the pigs would not be motivated to root if they were kept in fully slatted pens without any bedding. However, if rooting was internally motivated by rising hunger levels, then the pigs would be stimulated to perform rooting in a fully slatted pen just as much as in a natural environment.

Externally motivated behaviours can also be behavioural needs, when animals are kept in conditions where the external causal factors are present. Normally, such environments would permit expression of the appropriate behaviour, thus returning motivation to its baseline levels. However, behavioural needs may be unmet where the external causal factors are present but the means to carry out the behaviour are not - e.g. a tethered pig where substrate is available. It is also possible that some behaviours may be motivated by a combination of internal and external factors. For example, Jensen *et al.* (1993) suggested that the onset of nest building in free-ranging sows was internally motivated, but that the course of nest-building and maternal-oriented behaviours was more likely to be externally motivated. Causal factors for the internally motivated aspects were changes in hormones such as **prolactin**, whereas the course of nest building was more influenced by the level of protection offered by the nest site and by the materials available. Thus it is essential that the motivation and causal factors for each behaviour are thoroughly understood, but even then it may not be clear whether the behaviour is a need or not.

Another potential characteristic of a behavioural need is that the motivation to do it should build when performance is being denied. This relates to the classic model of **motivation** proposed by **Konrad Lorenz**, who suggested that motivation may be an accumulation of action-specific energy that is released when the behaviour occurs. Rising motivation during thwarted behavioural performance may be significant if this is accompanied by feelings of increasing frustration. Denial of behaviours motivated in this way would therefore result in a welfare problem that would increase the longer that an animal was kept in the deprived conditions. However, if this definition were to be used it would exclude some behavioural needs simply because motivation was already at a consistently high level and could not increase further.

Thus behavioural needs are behaviours that are important for the animal to perform even if its physiological needs have already been met, i.e. it is the performance of the behaviour that is important to the animal and not the outcomes of that behaviour.

Experimental techniques to examine behavioural need

Observation of natural behaviour

One possibility when trying to establish which behaviours are needs is to study animals in their natural environment and to record all the behaviours that they perform. This enables a complete behavioural repertoire to be established, which seems to be a logical starting point. However, a behavioural need is not proved by the performance of the behaviour in natural conditions, since it may be dependent on the presence of external motivating stimuli. Also, many of the behaviours that are essential for survival in the wild would not be needed in captivity. Thus, this technique enables identification of the behaviours an animal performs in the wild but gives no indication of the relative importance of different elements of the repertoire, especially under captive conditions.

Observation of behaviour when restricted

In order to rule out the issue of behaviours being stimulated by external stimuli that may not be present in captivity, the animal can be observed under specifically structured conditions. It has been suggested that behaviours that are performed even when relevant external stimuli are absent must have particularly strong internal causal factors and that this is evidence of behavioural need (Hughes, 1980). It has also been suggested that animals performing increased levels of exploration when deprived of a resource are demonstrating strong internal motivation to perform the behaviour involved. Nicol and Guilford (1991) compared the time spent exploring by hens deprived of feed, litter or neither. The deprived hens spent more time exploring in a tunnel that had no prior association with the resources, suggesting that they were internally motivated to seek them out.

P.53

This technique demonstrates that animals can have strong internal motivation for a given behaviour, even in the absence of external stimuli, making a convincing argument for it being a need in any environment. However the technique is limited to situations where behaviour-specific external stimuli can be systematically removed. It is also restricted to cases where it is still possible for the animal to carry out the behaviour, despite external stimuli being absent. As a result this technique has limited application.

Recording physiological consequences

It has also been suggested that recording the physiological consequences of not performing a behaviour would give an indication as to whether it is a need or not. Classic stress responses could indicate that frustration was resulting from not being able to perform selected behaviours, as could the occurrence of **abnormal** behaviours. However, this technique has the same limitations as that of observing behaviour in restricted conditions, i.e. that it is difficult to restrict only one behaviour and, if this cannot be done, then it is not possible to ascertain which restriction is causing the stress response. Therefore it is possible to reach only limited conclusions about many behaviours using this technique.

Performance despite physiological needs being met

Another possibility is to provide animals with their physiological needs and then see if they continue to perform the behaviour. As previously described, this has proved a successful approach with laboratory mice (Sherwin *et al.*, 2004). A similar experiment was carried out with hens by Hughes *et al.* (1989), which showed that nest-building behaviour was not inhibited by the presence of a preformed nest. This

suggests that the animals have a need to perform the behaviour as opposed to just requiring the outcome of the behaviour. However, in some instances the opposite is true. Gerbils' motivation to dig was noticeably reduced by the presence of a burrow (Wiedenmayer, 1997). In this case, provision of the outcome of the behaviour was sufficient for the animals, suggesting that digging behaviour was *not* a need. Overall, this technique seems to work well, but it remains restricted to goal-directed behaviours for which we are able to provide the outcome. It would, for example, be difficult to apply this method to examine whether there is a behavioural need for social contact. Secondly, we have to consider that this technique inevitably presents animals with external causal factors. Thus it is not possible to determine whether the animals would still be motivated to perform the behaviours in the absence of these stimuli. Ultimately, this method cannot tell us whether animals are suffering when they are kept in conditions without those external stimuli.

Consumer demand and behavioural resilience

The final method is to make animals work for the opportunity to perform different behaviours. By varying the amount of work that is required in order to gain the opportunity to perform specific behaviours, the strength of the animals' need for the behaviour can be determined. Alternatively, by measuring behavioural resilience or the inelasticity of demand, an assessment of the need for that behaviour or even a hierarchy of behavioural needs can be constructed (Young, 1999; and see: **Economics of behaviour**).

Thus, this technique has utility when examining individual behavioural needs. We can determine the relative strengths of an animal's need for a variety of behaviours at a particular point in time. However, it should be borne in mind that there will be variation in motivation at different times of the day, stages of life and so on. For example, sows will generally work hardest for food, except in the hours before farrowing when they are motivated to nest build, and will work equally hard for nesting material. Training the animals can be time consuming and outcomes have to be interpreted carefully, particularly since results are a continuum and a cut-off point must be defined in order to identify needs. Finally, as with the previous technique, the animal inevitably experiences the external stimuli, meaning that the conclusions about behavioural needs are limited when external stimuli are absent.

Alternatives to the concept of behavioural need

From this it can be seen that whether animals have behavioural needs or not is difficult to assess and therefore mention should be made of a different approach to the issue, which was raised by Hughes and Duncan (1988). They suggested that the problem for intensively farmed animals is not that they are unable to perform certain behavioural needs, but that they are unable to fill certain behavioural voids. So, for example, intensively kept animals have no need to find food, water or shelter as these are provided, and therefore their time budget is compacted. What may be important to the animal is how to fill the extra time available with the limited behaviours that they are able to perform within their situation.

P.54

Behavioural plasticity

Behavioural plasticity refers to the extent to which an individual can vary its response to a given situation. Plasticity may be used to refer to the level of change in a behaviour over time as a result of external feedback, i.e. the degree to which it is affected by learning. For example, fixed action patterns (FAP) are traditionally considered relatively non-plastic (or rigid), although it is now recognized that they do vary and adapt in response to **feedback**. This use is closely related to the use of the term plasticity in neurobiology in relation to synapses: synaptic plasticity refers to the extent to which the connection between two cells can vary, and so is closely linked to the processes of learning and **memory**. Alternatively, the term behavioural plasticity may refer to the ability of an individual to vary its response according to circumstances. For example, fight and flight are both responses to a potential threat, but one may be more appropriate than the other in a given circumstance. Some individuals may preferentially express one strategy over the other regardless of circumstances, and so their response is considered less plastic. In this context plasticity is closely linked to the study of **individual differences**.

Behavioural syndrome

The term behavioural syndrome derives from the use of the word 'syndrome' by evolutionary ecologists to describe packages of traits that go together (e.g. life history or migratory syndromes). For example, migratory syndromes occur in species where migrating individuals develop different groups of traits (or values of group traits) than non-migrants. A behavioural syndrome occurs when a population is comprised of multiple behavioural types. Individuals express behavioural types when they act consistently within and across functional contexts such as foraging or mating. The behavioural type is analogous to an individual's **personality** or **coping** style, and describes the manner in which the individual is likely to behave. For example, more aggressive individuals may engage in more agonistic interactions than less aggressive individuals, regardless of the circumstances.

This behavioural syndrome is marked by a correlation of behaviours within a single context over time or across contexts. For example, aggression and activity may correlate within a single context, with more aggressive individuals being more active and less aggressive individuals moving less. Across contexts correlations can occur if, for example, aggression in one context correlates with aggression in another. A key element of the behavioural syndrome is that individuals may occasionally act in a suboptimal manner. This suboptimality results because limited behavioural plasticity causes a carry-over of an individual's behavioural propensity from one context to another. The result is a **fitness** trade-off where individuals expressing one behavioural type fare well in one circumstance but worse in another. If individuals were unlimited in terms of **behavioural plasticity**, they would change their behaviour for each circumstance; this trade-off would not be observed and behavioural types would be uncommon.

However, behavioural types are noted in many species and the possibility for individuals to act in a manner that is more adaptive in some situations than in others thus occurs. For example, predators may easily notice the active individual that, even in the presence of predators, cannot reduce its activity level entirely. Thus, in situations where predators are common, active individuals may suffer higher mortality than less active individuals that are able to reduce their movements sufficiently to avoid being noticed. However, in an alternative situation where there are few predators, the active individual may locate and take advantage of food at a higher rate than the less active individual. In a behavioural syndrome then, the relative fitnesses of individuals vary within and between contexts.

In the applied sense, it may be useful to encourage the expression of behavioural syndromes in managed populations, be they wild or captive. Different behavioural types interact with their environment in different ways. The result of this differential interaction with the environment is that different behavioural types fill different portions of a species' **ecological niche**. For some individuals subtle changes

in environmental conditions can result in behavioural change, while for others extrinsic factors have little effect on behaviour. Alternative behavioural types may also have variant physiological responses to pathogens. For example, individuals that are more proactive or bold appear to be more susceptible to autoimmune disease than their more shy, reactive counterparts. These physiological differences occur in a number of measures and result in different behavioural types being more or less susceptible to various pathogens than others. Because behavioural types have different responses to environmental challenge, it is likely that populations that express behavioural syndromes are resilient to environmental challenge, as their members express varied responses to the challenge. Some of these responses may be effective in dealing with the challenge, while others are not. Conversely, populations with only one behavioural type may respond inappropriately and falter in the face of environmental challenge.

Programmes that raise animals for release to a protected wild environment may benefit from considering the behavioural types of animals destined for release. In the wild setting, animals must face challenges in a number of functional contexts. They must avoid predators and exploit food and occasionally food types with which they have no experience, and they must interact with familiar and unfamiliar conspecifics. Thus, in preparing animals for release, it may be most beneficial to consider their responses under an array of conditions. Those individuals that perform poorly at one task may excel at another, and these differences may be predictable based on the behavioural types of individuals. Because of these different responses of alternative behavioural types to environmental challenge, populations that express behavioural syndromes

P.55

may be more stable than those composed of individuals that are proficient at single, assumedly important tasks.

By promoting the expression of behavioural syndromes in managed populations managers can ensure that populations of concern are capable of dealing with a wide array of challenges. When animals live in social groups, alternative behavioural types are likely to fill specific roles within the group. Some individuals may be more likely to find and exploit new foods, while others may be more adept at locating predators and providing warning to conspecifics. Some behavioural types are more aggressive than others, and may be more likely to fight and gain dominant positions in the social hierarchy. In captive environments, the welfare of animals living in social groups may be enhanced if there is a mix of behavioural types that promotes decreased agonistic interactions in the group.

Behaviourism

Behaviourism (behaviorism) is a school in experimental psychology that focuses on the behaviour of the animal while avoiding the making of any inferences about the underlying processes. This is often called a 'black box' approach. The scientist studies the input, the stimulus, and the output, the behaviour or the response, without trying to understand what happens inside the animal. Because what is studied is the stimulus and the response, this has also been called an S-R approach to behaviour. The existence of internal processes is not denied but, since it was thought that they are impossible to investigate directly, they were excluded from study. This position has later been modified and the stance of behaviourism is today less rigid. Behaviouristic research focuses almost exclusively on the mechanisms of associative learning, especially operant conditioning.

Behaviourism as a school of thought was started in the USA in the early 1900s by the psychologist John B. Watson. It was founded as a reaction against the introspective approach of psychology, which relied on self-reports of mental experiences. The most famous behaviourist, **B.F. Skinner**, constructed a device in which the animal could perform a behaviour, e.g. pressing a lever in response to a signal. The pressing of the lever resulted in an event that could either be pleasant, e.g. food, or unpleasant, e.g. an electrical shock. The signal and the resulting event were controlled by a computer and the behaviour of the animal was registered automatically. This set-up came to be called a Skinner box, and has become a symbol for the behaviouristic approach to studying learning and behaviour.

Belly nosing

Belly nosing is the term given to the distinctive, rhythmic up-and-down snout movements performed by one piglet on the belly or flank of another piglet. Belly nosing and belly sucking are considered to be **abnormal** or **problem behaviours**, and are considered by some researchers to be **stereotypic** behaviours, although controversy about their **aetiology** remains. In piglets reared in semi-natural environments and subjected to the natural weaning process (gradual weaning between 7 and 17 weeks of age), belly nosing is rarely seen. However, it is relatively common on commercial farms, where piglets are artificially weaned (abrupt weaning and separation from the sow usually between 2 and 4 weeks of age). Belly nosing begins 3-5 days after weaning and rises to a peak incidence around 2 weeks later, followed by a gradual decline. It is also present in piglets artificially reared on milk replacer (i.e. non-weaned, but maternally separated piglets), can persist through the grow-finish phase and has been observed in both gilts and sows.

Belly nosing is characterized by high individual variation. Some piglets do not belly nose, some spend very small amounts of time belly nosing, and others spend a relatively large amount (as much as 8%) of their time belly nosing. As belly nosing is temporally transient post-weaning, it has been suggested as being redirected suckling behaviour (**see: Redirected behaviour**). A number of factors are associated with increased belly nosing incidence: age, genetics, suckling behaviour, growth and feed intake, feeding/drinking system and environmental enrichment.

There have been a number of studies that have shown that the age at which piglets are weaned has an impact on the amount of belly nosing observed during the post-weaning period. For example, two studies have shown that piglets weaned at 2 weeks of age show more belly nosing than piglets weaned at 4 weeks of age. Comparisons have also been made between piglets weaned at 4 and 6 weeks, piglets weaned at 2 and 3 weeks and piglets weaned at 1, 2 and 4 weeks. In all cases the younger the weaning age, the more belly nosing is observed.

There is some evidence that the genetic line of the piglet increases the likelihood of belly nosing being observed postweaning. A couple of studies have shown that Yorkshire/Landrace-type piglets show more belly nosing than Duroctype piglets. Also, in one of these studies, it was shown that the individual sire within the breed also had a significant effect on belly nosing incidence. Many authors have proposed that belly nosing is closely related to suckling motivation, and it would therefore perhaps be expected that those piglets that show high levels of suckling behaviour pre-weaning would show

P.56

correspondingly high levels of belly nosing post-weaning. In fact the opposite trend has been observed, with piglets that show low levels of suckling behaviour when with the sow showing more belly nosing post-weaning.

There appears to be no direct link between weaning weight and belly nosing, at least at the individual pig level, although it has been reported that lighter weight groups of piglets show more belly nosing than heavier weight groups, with weaning age being constant. However, a number of studies have demonstrated that piglets performing relatively high levels of belly nosing post-weaning have slower growth rates than their penmates. When piglets are abruptly weaned, they are usually transitioning from a milk diet to solid feed, although some piglets may have had access to solid feed prior to weaning (creep feeding). This usually results in a marked 'growthcheck' as piglets struggle to adapt to the dietary change, and those piglets that are slow to adapt to the diet presumably become hungry. A number of studies have noted that belly nosing is higher in piglets that have low feed intake, and there are significant negative correlations between time spent belly nosing and time spent at the feeder and time spent lying, and a positive correlation between time spent belly nosing and time spent active.

As to whether lack of feeding is driving belly nosing or vice versa, there is inconclusive evidence. Studies to date appear to suggest that when hungry, some pigs redirect foraging behaviour to pen structures, increasing rooting and nosing of the floor, whereas others appear to redirect to pen-mates and increase belly nosing. Belly nosing does appear to be related to the piglet's ability to perform natural sucking behaviours, as illustrated by studies on feeder and drinker design. First, where piglets are given access to nipples attached to a feed trough or access to an artificial udder that allows massaging and sucking, belly nosing is reduced. Also, the design of the drinker can influence time spent belly nosing, with water provided in drinking bowls apparently allowing piglets to satisfy the motivation to 'suck' better than water provided via nipple drinkers, thereby reducing belly nosing. Presentation of feed in a liquid form results in piglets spending less time belly nosing and more time lying resting compared with piglets fed a dry, solid feed - again, presumably by allowing piglets to suck during drinking.

The pig is naturally an inquisitive and exploratory animal, spending large amounts of time engaged in foraging-related behaviour. Within a commercial setting, many pigs are housed in relatively barren environments without any foraging substrates. It has long been known that pigs in barren environments

will spend significantly more time engaged in pen-mate-directed behaviours than pigs in enriched environments. Providing piglets with straw and/or other enrichment objects can reduce belly nosing.

In summary, although there have been a number of recent advances made in understanding the aetiology of belly nosing in piglets, the exact causation and functional significance of belly nosing remain to be elucidated.

Bentham, Jeremy

Jeremy Bentham (1748-1832) was an English philosopher regarded as the founder of a school of philosophy known as **utilitarianism**. He was the son and grandson of lawyers and it was intended that he should also be a practising lawyer. But Bentham was so disenchanted with the current state of English law that he turned to philosophy and the study of the theoretical foundations of a perfect system of law, and consequently wrote manuscripts on economics, politics, law and jurisprudence. In order to establish the foundations of a perfect legal system Bentham developed the principle of utility, known as the 'greatest happiness' principle, which, he held, rested on the undisputed natural fact that all living beings prefer pleasurable experiences over painful ones.

In the opening paragraph of the *Introduction to the Principles of Morals and Legislation*, Bentham states that: 'Nature has placed mankind under the governance of two sovereign masters, *pain* and *pleasure*'. This is not merely a factual statement; it informs us about what we ought to do. The principle of utility indicates that the right law will be that which provides the greatest amount of pleasure and, in its negative form, states that the right law will be that which minimizes misery and suffering. Pleasure and pain, being the ultimate measures of value, provide Bentham with guidelines for the well-being of all sentient creatures. Generally speaking it is the negative aspect of the principle that has provided legislators with guidelines: it is easier to establish consensus with regard to actions that alleviate suffering than those aimed at the promotion of pleasure.

Sweeping aside theoretical and theological foundations of morality in Chapter XVIII, Sec. 1., of the *Introduction*, Bentham posed the question of moral obligation towards all sentient creatures as follows: 'The question is not, Can they reason? Nor can they talk? But, *Can they suffer?*' [author's italics]. This doctrine has obvious implications for animal welfare, offering a moral dimension for scientific studies on the likelihood of pain and suffering among animals in our care.

Bentham's principle of utility underwent several modifications in the light of criticism. The doctrine of psychological hedonism which, according to Bentham, admitted no qualitative distinction between various forms of pleasure, was modified by his 19th-century successor John Stuart Mill, who introduced a distinction between 'higher' and 'lower' pleasures corresponding to mental and physical characteristics, respectively. Classical utilitarianism was further modified to avoid the accusation that its appeal to the consequences of an action supported the questionable doctrine that 'the end justifies the means'. Notwithstanding these modifications, Bentham's utilitarianism continues to provide a viable framework for proposed legislation regarding animal welfare.

Benzodiazepines

Benzodiazepines are a group of drugs that tend to be used for their inhibitory effect on the **central nervous system**, operating through the stimulation of benzodiazepine receptors

P.57

on the gamma amino butyric acid A receptor (**GABA^A** receptor). Benzodiazepine receptors are abundant in the central amygdala, along the ventral amygdalofugal pathway and within the anterior and medial **hypothalamus**, *substantia nigra* and peri-aqueductal grey (PAG), and so are closely associated with the **fear** response. Benzodiazepines also stimulate appetite, inhibit **memory** and can result in the disinhibition of **aggression**. They are dependence forming, and many animals treated with benzodiazepines in a clinical setting relapse upon the withdrawal of medication, and so their use without behaviour modification is not generally to be advised, unless being used concurrently to manage an acute crisis. Commonly used benzodiazepines include diazepam, alprazolam and lorazepam.

Bernard, Claude

An eminent French physiologist (1813-1878), whose work on living non-anaesthetized animals (**vivisection**) helped elucidate several physiological functions in the body. He started work as an aspiring writer but eventually was persuaded to study medicine. He then went to work with Francois Magendie, carrying out research into digestion and the pancreas, and eventually succeeded Magendie to the Chair of Experimental Physiology, where he was a proponent of experimental medicine on animals, so-called vivisection. He formulated the hypothesis of the internal **homeostasis** of the body (*milieu interieur*) that could be completely understood only in the whole animal. He was the first scientist in France to be granted a public funeral.

(DBM)

Beta-blocker

The term beta-blocker is used to refer to a class of drugs that antagonize (block) the beta-noradrenergic receptors (receptors of **norepinephrine**), which are found in both the **central nervous system** (these tracts run from the *locus coeruleus* to the cortex and from the lateral tegmental area into the thalamic

and hypothalamic regions and spinal cord) and peripherally in the **sympathetic nervous system**. Peripheral sympathetic arousal prepares the body for action by diverting blood from the viscera to the muscles and increasing cardiac output; centrally, noradrenergic activity results in changes in attention and memory that support this preparation process.

Blocking these receptors reduces the capacity to mount this response and has potential cognitive effects either directly or indirectly as a consequence. Alternative names for these drugs include beta-adrenergic blocking agents, beta-adrenergic antagonists, beta-adrenoceptor antagonists and beta-antagonists. The most commonly used beta-blocker is propranolol. They are used in animals not only in the management of heart failure, but also sometimes as part of the pharmacological management of fears in **companion animals** and may also be used (often illegally) in anxious animals at very low doses to improve performance. Their use for the management of fears is targeted at reducing the physiological response to the problem stimulus. Beta-blockers lower blood pressure because they relax both smooth (via beta-2 receptors) and cardiac (via beta-1 receptors) muscle, and this is a potentially serious side effect of its use in animals when administered for the management of fears.

Beta-endorphin

Beta-(or B-)endorphin is an endogenous opioid neurotransmitter 31 amino acids long, resulting from the processing of preprohormone **pro-opio-melanocortin (POMC)**. B-endorphin has the following amino acid structure: Tyr-Gly-Gly-Phe-Met-Thr-Ser-Glu-Lys-Ser-Gln-Thr-Pro-Leu-Val-Thr-Leu-Phe-Lys-Asn-Ala-Ile-Ile-Lys-Asn-Ala-Tyr-Lys-Lys-Gly-Glu.

The first five amino acids are common among several endogenous opioid peptides. This neurotransmitter works through both the **peripheral** and **central nervous systems** and is secreted from neurons of the **hypothalamus**, in the arcuate nucleus and the adenohypophysis of the **pituitary gland** following stimulation by the hypothalamic hormone **corticotropin-releasing hormone (CRH)**. B-endorphin acts via the opioid receptors and was initially described for its pain-suppressant effects. It acts naturally to reduce sensations of **pain** in animals over prolonged periods. Many narcotic painkillers work through the B-endorphin and other opioid receptors. B-endorphin response has also been shown to be initiated by other stressful and noxious stimuli such as exercise and foot shock. B-endorphins work primarily through the opioid receptor subtypes mu (μ) and delta (δ). Mu receptors were initially defined in relation to their morphine affinity. Along with B-endorphins, μ receptors also possess a high affinity for the opioid peptides **Dynorphin A** and the **enkephalins**. Delta receptors possess a high affinity for enkephalins and a slightly less high affinity for B-endorphins. Currently, δ receptors are less well defined than μ receptors.

Beta-endorphins are regulated by several neural and endocrine modulators. Activation of the **hypothalamic-pituitary-adrenal (HPA)** axis via stimulation of either **serotonin (5HT)-1A** or **5HT-2** receptors increases peripheral B-endorphin levels. However, antagonism of these receptors has not been shown to have an effect on plasma B-endorphin. Neuropeptide Y (NPY), another neural modulator of feeding behaviour, increases B-endorphin release from the basal hypothalamus.

Beta-endorphins have been shown to have a role in regulating **sexual behaviour and maternal behaviour**. A reduction in previously elevated B-endorphin levels in the brain just prior to parturition is suggested to

induce the onset of maternal behaviour. Studies using morphine to block the β -endorphin pathway have disrupted normal maternal behaviour and maternal aggression in lactating females, altered pup-cleaning behaviour and prevented the eating of the placenta in females post-parturition. β -endorphins have also been shown to facilitate the **lordosis** behaviour in sexually mature females. β -endorphins are also involved in male **sexual behaviour** - male rats administered opiate antagonist displayed significantly fewer mounting attempts and reduced latencies to ejaculation.

P.58

Opioids such as β -endorphin also have a role in feed intake and **feeding** behaviour. Reduction in β -endorphin levels causes a reduction in appetite or food-seeking behaviour. Studies have shown that mice deficient in β -endorphin have less motivation to work for food as a reward than wild-type mice. Conversely, fasting has been shown to increase hypothalamic and peripheral β -endorphin in animals, including pigs, but not pituitary concentrations. However, elevated pituitary concentrations of β -endorphin have been shown in genetically obese mice and rats. Lack of feed or energy from feed (such as from low-energy feedstuffs) is suggested as being the major cause for this increase. Studies of bulimia in human females have also shown a reduced β -endorphin reactivity in women with bulimia. Additionally, these studies have shown a negative correlation between β -endorphin levels and the severity of bulimia. β -endorphins may also play a role in the preference of more palatable foods. Mice fed diets consisting of equivalent energy, but superior and inferior palatability, have also shown reduced and increased levels, respectively, of gene expression of endogenous opioids in the hypothalamus. Similarly, increased β -endorphin binding was found in the hypothalamus of animals following a palatable feed reward stimulus. These data suggest a possible role for β -endorphin in the reward pathway.

Many researchers suggest that opioids such as β -endorphins may provide a superior measure of animal well-being than traditional **glucocorticoids** alone. Studies have shown that **transport** stress in swine has a strong affect on β -endorphin reactivity. Following a single transport of just 2 h, plasma β -endorphin levels were twice the pre-transport levels. Two transports were conducted when pigs were 18 and 20 kg, respectively. Although an increase in peripheral β -endorphin levels was detected following both transports, the second transport elicited a significantly smaller response than the first, suggesting an acclimation to this **stress**. Similar studies in sheep revealed no effect of transportation on β -endorphin levels, however. β -endorphins have also been established as indicators of social stress. Increased β -endorphin levels have also been correlated with low social rank in sows. Decreased μ opioid receptors in the brain have been shown in sows kept in isolation, while sows maintained at high density had increased density of μ receptors.

β -endorphins have also been shown to have a regulatory effect on **sleep**. A clear diurnal rhythm has been illustrated in humans, with β -endorphins at their peak levels between 04.00 and 10.00 hours, and at the lowest between 22.00 and 03.30 hours. Additionally, in cats, administration of excess β -endorphin has been shown to produce insomnia, inhibiting deep, slow-wave sleep and completely suppressing rapid eye movement (REM) sleep. Following treatment with excess β -endorphin, intermittent episodes of light, slow-wave sleep became the most commonly noted sleep stage. β -endorphin treatment, following treatment with a β -endorphin antagonist, reversed the insomnia effect of the opioid and returned the two stages of slow-wave sleep to control levels. However, REM-stage sleep was still suppressed even in the presence of an antagonist, suggesting a role for multiple opioid receptors in the sleep-wakefulness cycle.

β -endorphins in the periphery are synthesized in peripheral blood mononuclear cells. The concentration within the mononuclear cells is independent of the plasma opioid concentration. Stress is one of the most potent influences on the concentration of β -endorphins in mononuclear cells, increasing drastically with stressful stimuli. Increased peripheral blood mononuclear cell concentration of β -endorphins has been shown to inhibit normal immune function in both humans and animals. β -endorphins also play a role in

allergic response. Increased β -endorphin-like immunoreactivity has been shown in bronchial lavage sampling following grass pollen provocation in allergic subjects.

Beta-phenylethylamine

Beta-phenylethylamine is a monoamine synthesized in the body from phenylalanine and has mood-elevating effects in humans. It is a neuromodulator of dopaminergic systems in the **brain (see: Dopamine)** and is normally rapidly broken down by enzymes of the class monoamine oxidase-B. Primary interest in beta-phenylethylamine in applied animal behaviour relates to the use of the drug selegiline (1-deprenyl), which belongs to a class known as the monoamine oxidase-B inhibitors. It is a human antidepressant, also used in the treatment of Parkinson's disease, but is licensed in many countries for use in the treatment of animals with a range of emotional behaviour problems and **cognitive dysfunction**. Some of the effects of this drug may relate to the effects of phenylethylamine in the body.

Biodiversity

The word biodiversity (shortened from biological diversity) began to be used by environmentalists and conservationists in the 1980s to explain the variety of life on Earth. It considers the variety of life at different levels of biological organization including genes, species and ecosystems.

Biodiversity is most often understood in terms of the number of species within an area, region or the Earth as a whole. As of the first decade of the 21st century, 1.75 million species have been identified, and estimates for the total number in existence vary from 3 to 100 million. Biodiversity also includes genetic diversity within species: these are the small differences within an organism's DNA that makes it look and behave differently from all other members of its species. Genetic diversity is important, as it is the raw material for evolution by natural selection. Finally, biodiversity includes ecosystems: this is where communities of species, including humans, interact with each other and the environment around them. The habitats of the world, including forests, deserts, savannahs, freshwater and marine environments are all composed of many ecosystems.

The importance of biodiversity was one of the key subjects of the 1992 World Summit held in Rio de Janeiro, Brazil. World leaders discussed a strategy for sustainable development, and the outcome of this meeting was the Convention on Biological Diversity (CBD). One hundred and fifty government leaders

P.59

signed the convention, with its goals of 'the conservation of biological diversity, the sustainable use of its

components, and the fair and equitable sharing of the benefits from the use of genetic resources'. It emphasizes that 'biological diversity is about more than plants, animals and micro-organisms and their ecosystems - it is about people and our need for food, security, medicines, fresh air and water, shelter, and a clean and healthy environment in which to live'.

Unsustainable human consumption and poverty have caused huge losses in biodiversity; these include the disruption of ecosystem processes, habitat destruction, species extinction and the erosion of genetic diversity within species. The IUCN Red List of Threatened Species compiled by the Species Survival Commission of the World Conservation Union (IUCN) provides a measure of the conservation status of species, and this provides a direct measure of the threat that biodiversity is under. The 2006 Red List states that one-quarter of mammals, one-third of all amphibians and one-quarter of all coniferous trees are threatened with extinction.

Biodiversity is not distributed evenly throughout the world: in 1988 Norman Myers introduced the concept of biodiversity hotspots; these are areas with exceptionally high numbers of species found nowhere else (endemic) and very high levels of habitat loss. A number of conservation organizations, such as Conservation International, state that these areas should be conservation priorities. There are currently 34 biodiversity hotspots recognized, each holding at least 1500 endemic plant species and having lost 70% of their original habitat area. The hotspots include: Madagascar and the Indian Ocean islands; the coastal forests of Eastern Africa; the Caribbean Islands; and the Mediterranean Basin.

Bioethics

Bioethics is a branch of applied ethics dealing with ethical issues arising from human interference with biological processes. Bioethics was developed after World War II, and initially focused on the use of human subjects for experimentation, but the field has since broadened to cover issues raised by other applications of biology and various uses of biological resources, including animal use. Writings on bioethical issues are often informed by the author's commitment to a certain ethical perspective. Both religion and law help to shape the issues as well.

(PS)

Biophilia

Biophilia refers to the love of life, nature or living systems. Coined by psychologist Erich Fromm (1964) to capture the essence of humanitarian **ethics**, biophilia connotes a caring predisposition towards life forms that is manifest in risk taking to save an animal's life, for example, or in the positive emotion shown by adult mammals to certain traits of their young.

Two decades later, **E.O. Wilson**, an early and prominent advocate of the biological basis of all social behaviour (see: **Sociobiology**), published a small volume (Wilson, 1984) in which he postulated an innate human predisposition to love and care for nature that cannot be accounted for by science, money, power or culture. Rather, he argued, it is an emotion that appeared early in the human experience of being a part of nature and dependent upon it for survival. Humans arose out of nature. They gave names to its parts and assigned to them totemic value and supernatural power. Humans and other life forms are kin. In Wilson's words, an appreciation of nature's beauty can be said to lie in the genes of the beholder.

Modern humans' quest for open space in which to live, and the value assigned to a place with high vantage points and broken topography (i.e. an aesthetic view), are possible expressions of an ideal towards which they unconsciously strive. Cultivating ornamental gardens and placing flowers within our homes might give expression to an ancient attraction to a simpler and more spacious world. Biophilia cannot be scientifically proved, but many scientists who have focused on life and lifelike processes do not doubt its existence.

In the trammelled world of modern humans, biophilia is too infrequently evident. Yet, some argue it is humankind's best hope for its own future well-being, perhaps even its survival. Biophilia offers the best hope of conserving natural forms and systems that, in Darwin's phrase, offer a view of grandeur. The potential to respond to its inner force is there, as a substrate on which mental development can lead to love for nature. The time has come 'to invent moral reasoning of a new and more powerful kind' that reconnects us with nature and the values that will ensure that, in its grandest forms, it will always be with us.

Biostimulation

Biostimulation in relation to animal behaviour typically describes the positive effect of a male presence on female reproductive function. Several female reproductive variables can be affected - e.g. reduced time to sexual maturity, reduced postpartum or seasonal anoestrus, ovulation induction and improved sperm transport. Effects are most commonly mediated by olfactory cues through the release of what have been termed priming **pheromones**; however, other visual, tactile or auditory cues may also be effective. Biostimulation has been utilized in livestock husbandry to improve reproductive efficiency for a range of species.

(MRC)

See also: Sexual behaviour

Biotelemetry

Biotelemetry is the remote detection and measurement of an animal function, activity or condition. This includes a range of

P.60

techniques of varying invasiveness, including video monitoring, radio tracking and the use of remote data sampling systems. These sampling systems either transmit or store (log) physiological or behavioural data and may be mounted externally, e.g. using a harness, or internally by surgical implantation. Biotelemetry is used to obtain data such as heart rate, electrocardiogram, body temperature and blood pressure from experimental animals, commonly for fundamental physiology studies or in the process of pharmaceutical research and development or safety testing.

Biotelemetry can benefit both animal welfare and science. It can minimize or eliminate the need for external instrumentation and restraint, thereby reducing **stress**, and produce more relevant, better-quality data; this can in turn reduce the number of animals required for statistical significance. Telemetered data can also be used to provide evidence of animal well-being and to refine humane end points. However, there are a number of harms associated with biotelemetry: (i) surgical implantation or attachment procedures; (ii) the physical impact of the device on the animal; (iii) distress caused by housing animals individually, if devices are used that transmit at the same wavelength; and (iv) in studies using wild-caught animals, additional physiological and psychological stress and, if animals are released, reduced potential to monitor well-being and intervene if necessary.

There are a number of ways in which the impact of telemetry on experimental animals can be reduced. Devices can be selected and located so as to minimize their physical impact; good surgical technique and perioperative care, including analgesia, can significantly reduce postoperative discomfort or pain. Social species used in telemetry studies can be group housed, either by using data loggers, transmitters that can be switched on and off *in situ* and used one at a time, or the 'buddy' system, where implanted animals are housed with companions without working devices. It is important that all proposed projects involving biotelemetry: (i) are subject to a comprehensive ethical review that questions the necessity of the data; (ii) ensure that the least invasive method has been chosen to obtain data; and (iii) ensure that all techniques and husbandry have been fully refined. For wild animal use and field studies, researchers should be able to demonstrate that they have access to adequate resources and expertise to ensure that animals' lives and **well-being** will not be avoidably compromised.

Bite prevention programmes

Owning a **dog** has been proved to have multiple benefits for humans. Dogs can provide love, companionship and acceptance for all family members, particularly for children. Having a good relationship with a dog can help a child to overcome grief and sadness, and there is evidence that dogs play a positive role in child development. In addition, children who have pets engage more in social interactions and show more empathy towards peers (see: **Companion animal; Petting**). Nevertheless, owning pets may also present potential hazards through dog bites, trauma or zoonotic transmission of disease. It is estimated that each year in the USA 4.7 million people are bitten by dogs, with 800,000 bites requiring medical attention and 370,000 bites severe enough to be treated in emergency departments (EDs). Comparable ratios are found in Europe, with 250,000 people reported bitten annually in the UK and 100,000 in Belgium, the latter figure representing 1% of the population being bitten annually, and this figure has been rising annually in recent years. It is estimated that 50% of dog bites remain unreported, so the true scale of the problem remains difficult to quantify.

According to hospital-based surveys, it seems most dog bites happen in familiar surroundings, involving young children bitten by their own pet or a familiar dog, and 80-90% of the bites appear to be triggered by an interaction from the child towards the pet dog; these bites may result in signs of post-traumatic stress syndrome. However, in veterinary caseloads and otherwise-sourced bite report surveys, adults are reported to be the victim of dog bites twice as often as children. The fact that dog bites that happen in public places receive a lot of media attention may contribute to the perception of 'dangerous dogs' and dangerous breeds.

In non-industrialized countries, rabies causes 55,000 human deaths per year. Surveys indicate that bite accidents with domestic dogs are the source of infection for the vast majority (> 95%) of cases. In the Western world, dog bite fatalities are rare. In The Netherlands each year approximately one person dies following a dog bite, while 11 fatalities occur due to sport and 23 following household accidents. Unfortunately, the majority of victims of serious dog bites and fatalities are young children, triggering media emphasis on 'aggressive breeds', with the result that many governments have developed breedspecific legislation as a preventive measure. Recently, the advice that 'families with young children should stop keeping dog as pets' and 'a total ban on dog keeping' has been suggested in the medical literature.

In human preventive medicine it is recognized that only sustained interventions have sustained effects. Sustainability is enhanced by focusing upon underlying causes and contexts of behaviour and embedding or integrating prevention and promotion initiatives into ongoing systems, institutions and organizations, so that they become a natural part of people's everyday lives.

A dog's tendency to bite depends on multiple interacting factors related to heredity, early experience, later socialization, training and education, medical health, behavioural health and victim behaviour; these must be considered in the context of human social and cultural factors that have been shown to influence human-dog interactions. In the past, extensive information regarding interactions between dogs and children has been published in the veterinary and medical literature, and 'Prevent a Bite' programmes have been established in primary schools and healthcare centres in various European countries. Most 'Prevent a Bite' programmes, however, are aimed at the age group of 7 years and older and focus mainly on public safety rules, like how to behave when encountering

P.61

an unfamiliar dog. Programmes intended to prevent bite accidents in the home are very rare in Europe, although a CD-based training programme, focused on teaching appropriate behaviour towards dogs in the home for younger children (e.g. Blue dog; see De Keuster *et al.*, 2005), has recently been developed.

For the majority of risk situations, the message to the child is to encourage 'no' interaction, or 'leave your dog alone'.

In the past, dog bite prevention has generally been approached by teaching children skills on how to recognize the dog's body language. According to research, however, young children score badly in discriminating canine body language. Young children look mainly at the face of the dog in order to make their decisions. In addition, young children do not necessarily understand the dog's intentions: they will often confuse a fearful with a friendly dog. Therefore, rather than focusing on 'recognizing dog body language', it is potentially more useful to focus on teaching parents and children 'how to recognize and to assess situations that appear to trigger dog bites in a household situation'. Although there are commonly held beliefs and rules on safe play and safe petting of dogs, no data-based evidence exists on how to safely pet or how to safely play with the family dog. Thus it can be concluded that, for this issue, there are no rules applicable to 'the all-round family dog'. An alternative strategy is to improve parent awareness and knowledge of dog behaviour.

Bloat

Bloat, due to trapped gas in the stomach, can be observed as an acute swelling between the last rib and the hip on the left-hand side of a ruminant animal (in which it is also referred to as ruminal tympany), but may also affect certain monogastric species, such as the dog, when fed diets that produce a lot of gas. The animal is restless, finds lying uncomfortable and may eventually die of heart failure or suffocation.

Pasture bloat (also known as frothy bloat or primary bloat) in cattle is caused by stable foam in the rumen, which traps the gas that is normally released by eructation. The condition is often due to the rapid digestion of legumes in particular, although young, leafy grass that has recently received nitrogen fertilizer can also cause bloat. Lucerne is the most likely of all legumes to cause bloat, with cows sometimes dying within a few hours of entering a field for grazing. Some legumes have developed a chemical, tannin, which reduces the speed of protein digestion and probably discourages animals from grazing it. Tannins are present in sufficient quantities in birdsfoot trefoil to prevent the production of a stable foam, and the content in white clover increases sufficiently at flowering to make it safe to graze. If a mixed grass and clover sward has enough clover to cause bloat (probably more than 50% of the herbage by mass), it should not be grazed for long periods, but should either be conserved if there is sufficient mass or rested for a few weeks until the clover inflorescences appear, after which it can be grazed or conserved.

Cattle are most likely to become bloated in the late evening after a day's grazing, and also after a wet period when they avidly graze to make up for lost time. Wet grass reduces saliva production, and the saliva contains a mucin that disperses foam in the rumen. Herbage that has been frozen is particularly likely to cause bloat, as the rupture of plant cell walls releases the solutes that contain much potassium. Potassium-rich feeds, such as molasses, are well known for causing bloat, whereas grasses rich in sodium appear to be less likely to cause it. The precise mechanism has not yet been determined but may relate to the stimulation of saliva production by sodium-rich feeds and the foam-dispersing properties of the salivary mucin.

Forage supplements will usually slow down the rate of digestion and reduce bloat but, if there is adequate herbage, grazing supplements may not be eaten by some animals in sufficient quantities, particularly if they are based on straw or other low-quality forages. Mineral oils also help to disperse the foam and can be added to a concentrate feed, sprayed on to the pasture or, in the case of dairy cattle, applied to their flanks during milking to be licked off as needed; linseed oil is often used. A proprietary product, poloxalene, also breaks up the foam and can be used as a drench for clinical cases or included in feed blocks as a preventive measure. Often simply walking an animal from the field to the farm to receive medication may alleviate the swelling. It is important to keep a bloated animal on its feet if possible, as death can follow soon after recumbency.

There is a genetic component in the susceptibility to bloat, as well as reported breed differences in susceptibility; for example, Jersey cows are particularly prone to the disorder. Some species appear to be able to learn to tolerate feeds that are likely to cause bloat; this may be by altering their behaviour to spread their meals out more evenly over the day. Lactating cows are particularly susceptible due to their high intakes.

Pasture bloat remains a serious problem for farmers in countries like New Zealand, where the animals rely on pasture with little or no fertilizer applied and a high legume content. In Europe, the greater emphasis on controlling nitrogen emissions is encouraging farmers to use high-clover swards, potentially leading to more serious problems with bloat.

Obstructive bloat (also known as secondary bloat or free-gas bloat) occurs when gas cannot escape from the stomach due to physical obstruction and may, in theory, occur in any mammal. Often it is due to a foreign body (e.g. large piece of food such as a root vegetable) or twisting of the stomach (gastric torsion or volvulus), in which case it often requires surgical correction. The risk of twisting is increased in animals where the suspension of the stomach appears to be unstable, e.g. in certain deep-chested breeds of dog and animals that have undergone a period of starvation and so have an empty stomach.

P.62

Blocking

Blocking refers to a form of interference with classical conditioning (**see: Conditioning - types of**) that arises as a result of prior experience with a contingent predictor (**see: Contingency**) of an event. Once an animal learns that a given **stimulus** predicts a certain event, it becomes a conditioned stimulus for that event. If this stimulus is then reliably paired with another stimulus, which was not previously associated with the event, then the animal may fail to learn the new association, i.e. the second stimulus does not become a conditional stimulus and learning has been blocked by the presence of the first conditional stimulus. This may be because the new stimulus does not provide additional information that helps to predict the event beyond that which is provided by the first conditional stimulus, and so it is not salient. This phenomenon can give rise to problems when training, but this may be resolved by ensuring that the

potentially blocked stimulus is presented in advance of the blocking stimulus (i.e. the second stimulus is presented in advance of the already conditioned stimulus), so that it has predictive value and second order conditioning can occur. The phenomenon may also be useful because a conditional stimulus with a strong positive emotional association (e.g. a friendly owner) can be used to help block the learning of problematic behaviours associated with novel stimuli (e.g. a traumatic first experience at the veterinary clinic).

(DSM)

Blood pressure

Blood pressure (BP) is the pressure exerted by the blood on the walls of the blood vessels. Usually, when reported, it is the arterial pressure that is measured and reported as two numbers - the first being the systolic pressure (the pressure when the heart contracts and pushes blood out into the pulmonary artery and the aorta) and the second being the diastolic pressure (the pressure when the heart dilates and fills with blood). Pressure is conventionally reported in millimetres of mercury (mmHg), and an example within the normal human range would be 'one-twenty over eighty', or 120/80 mmHg meaning a systolic pressure of 120 mmHg coupled with a diastolic pressure of 80 mmHg.

Blood pressure can be measured either invasively (i.e. by inserting a measuring device into an artery) or, more commonly, non-invasively, by attaching a cuff externally and increasing pressure to occlude blood flow, before gradual release of the pressure to determine when blood is again flowing through the vessel of interest. Exact measurement may then be made by either listening through a stethoscope or using an oscillometer. For measurements in humans, the sphygmomanometer is still the most-used method, and comprises an inflatable cuff that is placed around the upper arm attached to an aneroid or mercury manometer. The cuff is inflated until the brachial artery is occluded and then pressure is released until turbulent blood flow can be heard through the artery. This pressure reading corresponds to the systolic pressure. Further pressure is released until turbulent flow can no longer be heard, with this reading corresponding to the diastolic pressure. Invasive techniques involve indwelling catheters or implanted radiotelemetry devices. For animals, the cuff technique can still be used, either on the tail or limbs, but for ambulatory studies invasive methods are more useful.

Blood pressure (mean arterial pressure (MAP)) can also be defined in terms of cardiac output (CO) and peripheral (or systemic) vascular resistance (SVR): $BP = CO \times SVR$. Cardiac output is itself a product of stroke volume (SV) and heart rate (HR), so $BP = SV \times HR \times SVR$. Systemic vascular resistance is related to the radius of the blood vessels and, indeed, resistance is inversely proportional to the fourth power of the radius (i.e. r^4). Thus, if the radius of the blood vessel is decreased by 50%, the pressure within it will increase 2^4 times = 16-fold. Not surprisingly, it is by altering the vessel radius (vasoconstriction and vasodilation) that the body controls blood pressure most readily, although it can also bring about changes by altering cardiac output. Normal blood pressure is maintained by a number of mechanisms, acting over both the short and long terms.

Short-term control of blood pressure is mediated by the nervous system, chemicals and hormones through alteration of systemic resistance within seconds or minutes. The **autonomic nervous system** is the most rapidly responding regulator of blood pressure, and receives continuous information from the baroreceptors (pressure-sensitive nerve endings) situated in the carotid sinus and the aortic arch. Ordinarily, with blood pressure at 'normal', the baroreceptors are firing at a steady rate, which is exerting a tonic inhibitory influence on sympathetic outflow from the vasomotor centre in the medulla. If blood pressure increases, the rate of firing increases, resulting in a decrease in sympathetic activity and an increase in parasympathetic activity, which together will act to decrease cardiovascular output by

increasing heart rate and to decrease peripheral resistance by vasodilation. Changes in the opposite direction occur if blood pressure falls below 'normal'.

Chemoreceptors situated in the aortic arch and carotid body can respond to changes in blood PO_2 , PCO_2 and pH. A decrease in carotid body blood flow results in cellular hypoxia, hypercapnia and decreased pH, leading to an increase in receptor firing. The threshold PO_2 for activation in humans is about 80 mmHg (normal arterial PO_2 is about 95 mmHg). Any elevation of PCO_2 above a normal value of 40 mmHg, or a decrease in pH below 7.4, causes receptor firing. If respiratory activity is not allowed to change during chemoreceptor stimulation, then chemoreceptor activation causes bradycardia and coronary vasodilation (both via vagal activation) and systemic vasoconstriction (via sympathetic activation). If respiratory activity increases, then sympathetic activity stimulates both the heart and vasculature to increase arterial pressure.

Hormonal mechanisms exist for both lowering and raising of blood pressure. They act in various ways, including vasoconstriction, vasodilation and alteration of blood volume. The principal hormones affecting blood pressure are:

1. **Epinephrine** (adrenaline) and **norepinephrine** (noradrenaline) are secreted from the adrenal medulla in response to **sympathetic nervous system** stimulation. They increase cardiac output, causing vasoconstriction, and act very rapidly.

2. Atrial natriuretic peptide (ANP) is produced, stored and released by cardiac myocytes in the atria of the heart. It is released in response to atrial stretching. ANP binds to a specific set of receptors - ANP receptors. Receptor-agonist binding causes a reduction in blood volume and therefore a reduction in cardiac output and systemic blood pressure.

P.63

3. **Antidiuretic hormone** (ADH or arginine vasopressin), secreted from the posterior pituitary gland, increases the resistance of the peripheral vessels and increases arterial blood pressure.

4. Endothelial factors have an important role in the regulation of smooth muscle function. The three most important endothelial-derived substances are: nitric oxide (NO), endothelin (ET-1) and prostacyclin (PGI_2). NO and PGI_2 act as vasodilators, whereas ET-1 serves as a vasoconstrictor.

Over the longer term, blood pressure control is a function of renal mechanisms that regulate blood volume. Directly, any increase in blood volume and blood pressure will result in an increase in the rate of fluid removal by the kidneys, leading to decreased blood volume and decreased blood pressure. If blood volume and blood pressure decrease, the kidney will conserve and return more fluid, thereby increasing blood volume and raising blood pressure. The other major renal mechanism is the renin-angiotensin-aldosterone system (RAAS). When blood pressure drops, the juxtaglomerular cells of the kidneys secrete renin, which cleaves a peptide bond in angiotensinogen to create angiotensin I. This is then converted to angiotensin II in the lungs by angiotensin-converting enzyme (ACE). Angiotensin II is a strong vasoconstrictor which also stimulates the adrenal cortex to release aldosterone, which itself works to reduce the excretion of sodium and reduce water loss, thereby increasing blood volume and raising blood pressure.

As a welfare indicator, blood pressure has not been used extensively due to methodological limitations. It has been used during studies of restraint and slaughter, but not in animals in free-ranging situations. With the development of telemetric implants with blood pressure capability, blood pressure is likely to attract more research attention in the future.

(RM-F)

Body condition score

Body condition score (BCS) is a subjective, non-invasive assessment tool used to describe the level of body fat and muscle in animals. Generally, low body condition scores reflect emaciation while high values are associated with obesity. Body condition scores are used to monitor and manage nutrient requirements, to estimate body fat prior to slaughter and as an indicator of the level of feeding.

Scoring systems are available for a range of animals including **cattle, sheep, horses and chickens**. BCS is based on visual and/or tactile assessment of the fat/musculature in single or multiple regions of the body. The body regions included in the score differ between species and scoring systems, but BCS is often based on the amount of fat/muscle covering bony protuberances, such as the ribs. Scoring systems characterize body condition into discrete categories. The categories can be as few as 3, but 5-, 6- and 9- point integer scales are common. Although body condition scoring systems differ in methodology, there is often good agreement between the attributed scores in different systems, for example in dairy cows (Roche *et al.*, 2004).

Regardless of the scoring system used, the repeatability and validity of BCS affects its usefulness as an assessment tool. BCSs can be assigned consistently across observers (e.g. Edmonson *et al.*, 1989; Teixeira *et al.*, 1989), although training and experience can have a major influence. Body condition scores have been compared to more quantitative measurements of condition, including ultrasound, live weight and percentage of dissected fat, empty body weight, muscle weight and dewlap thickness (e.g. Teixeira *et al.*, 1989; Domecq *et al.*, 1995, Gregory *et al.*, 1998). In addition to the relationship between BCS and other measures of condition, body condition affects aspects of biological function, such as reproduction (e.g. number of live offspring, time to conception).

Body weight - metabolic

Metabolic body weight (also known as metabolic weight) considers the relationship between body weight and metabolic rate in homeothermic species, and is used in the calculation and prediction of energy and other requirements related to the rate of metabolism of an animal. There is not a linear relationship between metabolism and body weight, since smaller animals are relatively speaking much more metabolically active than larger ones. This is mainly due to the relationship between surface area and volume, since much energy is lost as heat through the surface area of an animal, and the ratio of surface area to body volume decreases with increased size. A plot of the log of body weight against the log of heat production for various homeothermic species produces a straight line, and so the metabolic body weight of an animal is its body weight to the power of 0.75 ($BW^{0.75}$). It is calculated that the metabolic level of adult homeothermic mammals is approximately 70 kcal/kg^{0.75}.

Bonding

Bonding relates to preferential social relationships that can be established between individuals. Bonds can develop between various types of partners, such as mother and young (see: **Bonding - parent-offspring**), mates (i.e. pair bonding), brothers and sisters, other non-kin conspecifics and even individuals from different species (e.g. the human-animal bond). Several elements are necessary for a bond to be established. The individual should first be motivated to

P.64

approach and interact with another individual whom they should then subsequently be able to recognize, and selective positive interactions should then be reinforced. **Oxytocin** and vasopressin have been demonstrated to play a major role in all these stages.

The capacity/tendency to form social bonds stems from interactions between genetic and developmental processes. It can vary across species and may lead to a range of social organizations from solitary animals to extended family groups. Bonding is also influenced by gender, physiological state, previous experience or emotional context - for example, stress has been shown to facilitate social bonding.

The existence of preferential social relationships can be assessed through the use of behavioural observations. A selective approach in partner **preference tests (choice test)** is a widely used criterion. The animal is given a choice between different kinds of social partners (e.g. two familiar individuals or a familiar individual versus a stranger), and the time it spends in proximity with each partner is recorded. The maintenance of physical proximity or contact and positive social interactions (e.g. **allogrooming**) are also considered as being indicative of social affiliative relationships. Other parameters, such as the reactivity to separation from the partner, as well as its appeasing effect in a challenging context, can also be used to assess bonding. Social bonds can benefit the animals in numerous ways. The mother-young bond or the pair bond are of evident advantage in terms of survival and reproduction, and social bonds can more generally reduce anxiety, help recovery following challenging events (i.e. social buffering) and provide support during social interaction. The disruption, as well as the absence, of social bonds can thus be of much welfare concern.

Bonding - parent-offspring

In most animals it is the female parent, rather than the male, that normally becomes most closely bonded to the offspring, by virtue of her greater investment in the nurturing and birth of the offspring. Bonding develops soon after birth and, given the opportunity, will persist as a matriarchal family group. The initial bonding has the following characteristics. It develops during the **sensitive phase**, which for a precocious animal such as *Bos taurus* occurs in the immediate postnatal period. It is permanent and irreversible, but its strength will depend on the extent of other imprinted bonds the dam has. A cow with twins therefore develops a weaker bond with each calf than a cow with a single calf, and this encourages the twins to form sibling bonds. Within a semi-wild herd of cows and calves, the bond between dam and daughter will persist as the dominant social force, and the males disperse to form bachelor groups. Equal preference is generally given by the dam to her offspring, regardless of their age and sex.

However, a number of factors may affect the strength of the imprinting process. Multiparous cows form stronger bonds than primiparous cows, through greater contact and contactseeking behaviour with their calves, and they are more disturbed by separation. Primiparous cows show more abnormal maternal behaviour but spend longer suckling their calves than multiparous cows, but this may simply be due to slow milk excretion rather than to more investment of time to enhance the bond. The creation of a strong maternal-filial bond is a learned characteristic, although much of the stimulation by the calf is innate. Intensely selected dairy breeds, such as the Holstein-Friesian, show weak dam-filial bonding. They are more easily cross-fostered (**see: Fostering**), and removal of the calf for artificial rearing has little effect on its temperament, whereas in less developed cattle breeds such as the Salers, artificial rearing reduces the social adaptability of calves.

The bond is naturally created at a time when the neonate is drawn to the dam by suckling motivation, and the chances of other bonds being created during the period of primary **socialization** are small. The bond is preserved by **grooming**, both during and after suckling, but other forms of communication like **vocalization** must be important, since calves that are muzzled to prevent suckling and grooming still develop a bond with their dams. The bond, and in particular suckling, maintains the postpartum anoestrus in cows for about 8 weeks to prevent early rebreeding.

The benefits of a strong mother-filial bond are many, particularly in wild animals, where the dam needs to teach the offspring how to survive. For the neonate, filial imprinting, which underpins the bonding process, may provide the basis upon which the young learn the characteristics of their species. There are many sources of reward provided through the bond: for example, reward may come in the form of protection and nutrition in the form of milk. Early licking of the perineal region stimulates the functioning of the gastrointestinal tract and excretion. Later, the juveniles learn dietary and other habits from their dams and may acquire a stable position in the group structure dependent partly on their dam's position.

Bone strength

Bone strength is a term used to refer to the bone density and the architecture of a given bone. Bone strength can be affected by a multitude of factors, including nutrition, stage of production, age and mechanical stress. To understand how bone strength is controlled, it is important to understand the mechanisms of bone degradation and rebuilding.

There are three main types of cells that make up the bone. Osteoblasts are bone-formation cells and osteoclasts are boneremodelling cells. Osteocytes are the functional cells of bone and are responsible for responding to mechanical stimuli by initiating either bone formation or remodelling by chemical messengers. Osteoclasts and osteoblasts act concurrently in continually remodelling bone to keep the architecture of the bone sufficient to support the mechanical stress to which it is subjected. Constant remodelling also serves to help maintain plasma calcium concentrations. Several hormones are responsible for the initiation and regulation of both osteoclasts and osteoblasts. The sex hormone oestrogen stimulates osteopro-togerin

P.65

(OPG) in both males and females to inhibit osteoclast activity. Thyroid-stimulating hormone (TSH) also plays a role in the stimulation of both osteoclasts and osteoblasts. In order for growth to occur, osteoblastic activity must be greater than the osteoclastic activity. Both **growth hormone (GH)** and **insulin-like growth factor-1 (IGF-1)** control the activity of osteoblasts during growth phases. Bone remodelling occurs throughout an animal's lifetime but slows with age.

As previously mentioned, there are several factors that affect bone strength. These factors are common among species and are described below.

Nutrition

Calcium is a vital component of bone, especially bone mineral content and bone density. Ninety-nine per cent of the body's calcium is stored in the bone as hydroxyapatite. Plasma calcium concentrations are controlled by the peptide **parathyroid hormone (PTH)** from the parathyroid glands. PTH controls calcium from the intestines and kidney and is capable of releasing calcium from bone. Adequate calcium intake throughout life, particularly during adolescence, is vital in developing and maintaining bone density. Inadequate calcium concentrations during development inhibit the skeletal system from reaching maximal bone density.

Production

At different stages of production, demands on the body are different. In gestating and lactating mammals and egg-laying birds, the calcium requirement is high and bone calcium reserves may be used to meet the demands of the developing fetus and milk production and eggshell production, respectively. In chronic calcium deficiency, bone calcium will be used to replenish plasma calcium concentrations. In the event that calcium is not replenished to the bone, long-term effects on bone strength will result. The use of bone calcium reserves will decrease bone density, increasing the females' susceptibility to fracture and other bone injuries. In most mammalian species, there is a short period between lactation and gestation of the next parity. This may not allow the female to replace the bone reabsorbed during the previous gestation or lactation, causing increasing bone loss. For egg-laying hens, egg production is continuous throughout their productive life from 18 to 22 weeks of age, and up to 60-70 weeks of age and longer for moulted birds. Hens at the end of lay are particularly susceptible to broken bones during removal from the laying house and transportation to the slaughter plant.

In animals raised for meat production, such as slaughter pigs, turkeys and broilers, high growth rates may not allow the animal ever to reach maximal bone density. If bone density is not sufficient, the risk of bone problems increases, thus increasing the risk of lame animals.

Mechanical stress

One of the primary ways in which bone is deposited and reabsorbed throughout an animal's life is in response to mechanical stress on the bone. Wolf's Law is a principal law in bone physiology, stating that bone responds to the forces placed upon it. In conditions of high mechanical stress, osteoblast activity will increase to deposit more bone to compensate for the added stress. In sedentary animals where mechanical stress is lacking, such as sows in stalls and hens in cages, osteoclast activity will increase, depleting the bone density. Short, dynamic exercise with rest periods between exercise bouts has been shown to significantly increase bone density. Animals that are kept in confinement may not be able to exercise enough in order to maintain or increase bone density.

Age

Bone modelling and remodelling occurs at a higher rate throughout adolescence until maturity. At maturity, bone activity tends to plateau and slowly decrease with age. As mentioned previously, the amount of bone deposited during adolescence and maintained during adulthood primarily depends on nutrition and mechanical stress on the bone. The sex hormone **oestrogen** also plays an essential role in bone formation during adolescence and bone maintenance in adult animals. Oestrogen is responsible for the closure of growth plates in adolescent males and females. In adult animals, oestrogen deficiencies can also cause considerable loss of bone, resulting in osteoporosis. This loss of bone may render the animal more susceptible to becoming lame.

Genetics

Like most traits, bone density is a genetically influenced trait. Bone strength can differ between breeds of the same species and between individuals of the same genetic line. Selective breeding is a common practice in which animals are bred to enhance a certain trait, such as muscle weight or height. With selective breeding of such traits, bone strength can be improved or negatively affected. With traits that increase growth rate or overall size of an animal, there is a risk of decreasing bone strength, not only by genetic factors but by the fact that the bone may be deposited at a slower rate than is muscle. This again can lead to leg and skeletal problems and increase the risk of lameness.

Boredom

Boredom is a negative subjective state, defined by Webster (2005) as 'a sense of unease associated with the absence of any specific motivational need'. Although originally a phenomenon described in humans, boredom is increasingly being considered when assessing **welfare** in captive animals. Boredom is envisaged as resulting from a chronic lack of opportunity for active interaction with the environment (Wemelsfelder, 2005), and it has been suggested that animals housed in barren forms of farm, laboratory and **zoo** housing are at most risk of experiencing this unpleasant state (**see also: Allostasis**).

The impact of housing animals in a barren environment can be examined objectively by comparing their physiology and behaviour with animals housed in more complex environments. Behavioural changes associated with barren environments include more time spent sitting, lying and sleeping and more fearful or aggressive responses to novel or unpredictable stimuli. Other problems are also well documented. These range from **stereotypies** to self-injurious behaviour, **aggression** and even **cannibalism**. Another way of examining the impact of a barren environment is to determine whether animals will work to access more stimulating environments.

The phenomenon of **contra-freeloading** shows that animals will sometimes choose to work for food even when presented with 'free' food of the same value. Similarly, animals will explore novel objects that are of no biological relevance to them, suggesting that they do so to seek stimulation.

However, although such studies are useful, we must remember that barren environments may exert their effects in many ways (e.g. by increasing **stress** levels), and the appearance of **problem behaviours** is not, in itself, good evidence that animals feel bored. There may also be cognitive constraints on the extent to which animals can choose to be in a variable environment. Although hens can assess the future consequences of their choices this is generally done over very short time periods, indicating that animals may not always make the best choices for their long-term welfare.

Human studies have shown that the propensity to experience boredom is influenced by both internal and external factors, and that this tendency changes at different stages of a lifetime. External factors are thought to influence boredom largely when a discrepancy arises between an animal's current environment and the one to which it is evolutionarily adapted. A simple model was proposed by Webster (2005) in his adaptation of one of McFarland's motivational models (**see: Motivation**). In this model (Fig. B.1), the distance from the centre relates to the level of motivation associated with a given state, and at any given time an animal will be at a given point in this multidimensional state. As one need is satisfied, so its state regresses towards the centre for that dimension and another will take priority. For example, a very hungry animal that is quite tired could be placed somewhere between H" and R in Fig. B.1, and will feed rather than rest. As it feeds, so hunger falls along the axis through H to H' while exhaustion remains around the limit of R, and it will then rest. 'Limbo', a state caused by the absence of normal environmental challenges, was envisaged as the motivational state most likely to be associated with a subjective feeling of boredom in captive animals. Webster (2005) used an extension of the surface including H'-R', which extends to the other motivational states (see Fig. B.1), to demonstrate how a cow in a solitary stall may enter the state of limbo. The cow has everything she needs and will not suffer from exhaustion, hunger or thirst, nor will she be exposed to any of the challenges around the sides of McFarland's 'egg'.

This line of reasoning is brought into focus when we compare the lives of domestic animals with those of their wild ancestors. Junglefowl (*Gallus gallus*), the wild ancestors of domestic chickens (*Gallus gallus domesticus*), for example, spend a large amount of time each day locating and consuming food, checking for predators, building nests and competing for resources within a complex social hierarchy. These behaviours take place within a complex jungle habitat, with varying temperature and light levels. In contrast, most domestic chickens are kept in flocks of the same age and genetic background, in predator- and weather-proof buildings and are provided with *ad libitum* high-quality feed. The behavioural void, or limbo, left by housing chickens in this way is likely to lead to reduced welfare, but whether this ultimately results in a feeling of boredom would depend on whether chickens have sufficient neural complexity to experience complex secondary emotions.

Like all subjective experiences, boredom is impossible to measure directly. Findings from human studies have revealed that boredom is an 'extremely unpleasant and distressing experience'. Although many believe that most vertebrates are indeed likely to be capable of experiencing this kind of negative state, it is salutary to consider that we know little about the psychological constructs required for the sensation of boredom. Presumably, a complex secondary emotion such as boredom depends on a certain level of emotional and cognitive complexity and possibly some degree of self-reflective **awareness** (or **sentence**). Whether an animal is considered as sentient might play a large part in whether it is capable of experiencing boredom. Humans might become bored because they consider that the situation they are currently in differs from an imagined situation that they might like to be in. Therefore, the degree of sentence and the ability to reflect on current status versus the alternatives might be limiting factors in whether or not an animal is capable of experiencing boredom,

rather than a simpler, primary emotion, such as frustration.

Until the psychological constructs that support subjective states such as boredom are better defined, we may have to resort to drawing analogies between our experience as humans and that of animals. For example, we might get bored sitting in an empty room all day with nothing to do, and so might imagine that a chicken, with no species-specific stimulation, would also be bored. Some scientists believe that this method is **anthropomorphic** and inappropriate because of different cognitive abilities and requirements; others would claim that it at least gives the animal the 'benefit of the doubt'. A final approach is to consider whether boredom might have an adaptive function. Boredom could force animals to explore, learn and familiarize themselves with their environment and, through this, to adapt to challenges within it. Animals in different ecological niches, social animals or animals that have large home ranges could therefore experience different forms of boredom when confined in captivity. In addition, domesticated animals, or individuals housed in barren environments all their lives, might differ in their propensity to experience boredom.

In conclusion, the term boredom originated to describe our own human experience, but there has been little if any progress in identifying reliable physiological or behavioural correlates of these human feelings in non-human animals. Unlike feelings associated with emotions such as **frustration**, **fear** or anxiety, it is therefore difficult to identify which animals might share a feeling of boredom. It has been proposed that animals may feel bored when there is reduction in stimulation between what an animal expects from its environment (the environment it evolved in) and what we, as humans, provide for the animal (its captive environment). However, the use of the term animal boredom remains vague and testable predictions elusive. Further research and integration of objective measures could allow us to make inferences about whether an animal is bored, and might allow us to seek methods to alleviate that boredom and to improve welfare.

Brambell Report

The Brambell Committee was a technical committee set up by the UK government to investigate the welfare of animals kept in intensive livestock production systems. They published their influential report in 1965 and this, along with the publication of **Ruth Harrison's** *Animal Machines*, was thought to be one of the main factors responsible for the initiation of specific farm animal legislation in the UK. The report discussed many of the potential welfare concerns associated with modern farming, identified the most serious threats to farm animals and made recommendations as to which practices should or should not be allowed to continue.

Branding

Branding serves as a method for permanently identifying animals (usually livestock) in a way that is difficult to modify or falsify. Such a form of identification is important for proof of ownership and for trace-back, for example in the event of outbreaks of disease. For these reasons, in some countries branding is a legal requirement for certain classes of livestock, e.g. those over a specified liveweight being presented for sale.

Branding is normally conducted by one of two methods: heating (hot-iron branding) or cooling (freeze branding) of the skin. Brands are generally applied to the body of the animal (rump, ribs, shoulder), although with concerns for hide quality there has been a move to locate brands in positions that cause less damage to and/or loss of hides. Hot-iron brands are also used to mark the horns of animals such as stud sheep.

Hot-iron branding

Hot-iron branding is conducted by heating a branding iron, either by an internal electrical element or by placing it in a furnace or fire to a point where it glows a dull red (in excess of 500°C). The hot iron is then placed on the body of a suitably restrained animal for about 3-5 s. The visible brand that results is a hairless area of scar tissue. Performed correctly (i.e. the branding iron at the correct temperature, applied with the correct amount of force and for the correct length of time), hot-iron branding should burn the skin through to the dermis, producing a third-degree burn. Third-degree burns destroy the pain receptors in the burnt tissue, so that noxious sensory inputs are reduced. In humans, third-degree burns are reported to be much less painful than first- or second-degree burns that leave many pain receptors intact. However, at the periphery of third-degree burns will be first- and second-degree burns that probably cause the inflammatory responses and longer-term **pain**.

Freeze branding

For freeze branding the branding iron is chilled in a coolant, such as liquid nitrogen (-196°C) or dry ice in alcohol (-70°C) and it is then placed on a shaved area of the hide for 15-30 s until the skin is frozen.

Another technique involves a stencil

P.68

held over a shaved area of the hide and an aerosol spray of a chemical coolant (e.g. chlorodifluoromethane), which cools the skin to about -50°C. Freeze-brand marks take about 1 month to become visible; either the pigment-producing cells or the hair cells are destroyed and the hair grows white permanently or falls out, depending on whether the application time is short or long, respectively. If pigmentation changes are induced then, evidently, freeze branding is suitable only on dark-coloured animals. As a result of the increased restraint time and handling of animals to produce the brand and difficulties in obtaining and storing the coolant in remote areas, freeze branding is less popular in remote areas than hot-iron branding, particularly when large numbers of animals are being branded.

Research on branding in cattle has investigated changes in behaviour, **heart rate**, plasma cortisol, adrenaline and noradrenaline levels as indicators of pain and **stress**. Most studies have investigated only the short-term responses to branding and have compared hot-iron, freeze and sham (the branding iron at ambient temperature) branding. Based on the measures taken, both hot-iron and freeze branding procedures are stressful and painful, although the stress appears not to be severe and the pain relatively short-lived. Hot-iron branding is probably more painful than freeze branding, although some work indicates that the pain from freeze branding may last longer than that associated with hot-iron branding. Studies that have investigated the hide surface temperature in the vicinity of the brand demonstrated elevated temperatures for up to 7 days post-branding, but with higher temperatures at the freeze brand sites compared with the hot-iron brand sites in the first 2 days. One study found that the temperatures of sites for both methods peaked at 48 h post-branding and there was no difference between the two methods until 6 days post-branding, when the hot-iron brand sites were warmer than those of the freeze brand. Hot-iron brand sites were also warmer than control sites at 7 days post-branding but freeze brand sites were not.

These results have been interpreted as corresponding to the differences in damage caused by the methods of branding and the duration of the inflammatory response, with the **inflammation** giving an indirect 'measure' of pain and discomfort. Interestingly, another study found that there was no difference between hot-iron, freeze and sham branding in the sensitivity to touching the branding site 1 and 7 days post-branding.

The longer-term effects of hot-iron and freeze branding have also been investigated. Branding appeared not to be a sufficiently stressful procedure to induce illness or disease in the animals (as assessed by the level of antibiotic treatment of animals), and did not influence body weight gains over 10- and 28-day periods post-branding.

It follows that, as both hot-iron and freeze branding cause pain as a result of tissue damage, pain will be reduced by using small, single-piece brands compared with large and/or multiple-piece brands.

One interesting finding from some of these experiments relates to the **stress** induced by **handling** and restraining animals that are unaccustomed to it. In one study, plasma cortisol concentrations and heart rates of beef calves rose when handled and restrained, regardless of the branding method. In contrast, when dairy cows that were accustomed to being handled and restrained were branded, their behavioural and physiological responses were attenuated, although measurements still indicated that hot-iron branding was more painful and stressful than freeze branding, which in turn was more painful and stressful than sham branding.

The stencil and aerosol coolant method was investigated in a study with horses and produced only 'mild' reactions. However, the brands produced were of poor quality.

A third method of branding that has been used, although rarely, is the application of caustic chemicals. This method is banned in many countries on animal welfare grounds. However, it should be possible to use non-caustic chemicals to inhibit melanin synthesis in the pigment-producing cells. In one study a range of such chemicals was applied topically or by intradermal injection to cattle, but most were ineffective. Furthermore, there were problems with the chemicals causing necrosis of tissue.

Breed

Variation between individuals of a species is a driving force of natural selection. Under natural situations factors, such as geographical isolation, can lead to natural selection producing populations of a species that exhibit distinctly different characteristics from other nearby populations of the same species. This variation is usually described in terms of **subspecies**.

Variation is also a characteristic of populations of domesticated animals, and artificial selection by humans has led to the development of distinct breeds. A breed is a group of animals that has been selected by man to possess a uniform appearance that is heritable and distinguishes it from other groups of animals within the same species. Small changes in the body plan, pelage or behaviour of an individual of a species can be considered desirable by humans. Such differences can have a functional aspect or can be simply aesthetic. Much variability in a population of animals is due to genetic mutations within individuals. Some kinds of genetic variation in a species are not discrete, and often over a wide geographic area different populations of a species interbreed to produce a **phenotypic cline**. Breeds, therefore, reflect human exploitation of the natural variability of domesticated species.

Breeds are typically associated with 'animal partners', e.g. dogs, **cattle**, **sheep** and **horses**, that have undergone complete domestication and changed in morphology and behaviour from their original progenitor species. In farm animals, breed development invariably enhances desirable production traits. In **companion animals**, e.g. **cats**, **rabbits** and **rodents**, breed development largely enhances aesthetic characteristics, producing breeds that exhibit particular colour combinations or pelage types. Humans have not exposed 'exploited captive' species, e.g. camels and elephants, to any significant selection pressure and so they tend not to exhibit breeds.

Numbers of breeds of cattle, equines, goats, pigs and sheep that are recognized to have arisen in Africa, Asia and Europe are significantly correlated with the size of the human population. Similar results were found for states within countries like Russia, India and China, but correlations were weaker for land areas. Therefore, conditions that favour human population growth also favour breed diversification.

Geographical location is important in breed diversity; countries

P.69

with the most breeds per million people are more remote. Even within the UK, Scotland and Wales have many more breeds of livestock per million head of the population than England. Breed diversification is, therefore, more likely in remote or difficult areas of the globe.

Development of breeds has a long history. For example, dogs that are recognizably hounds are depicted on Ancient Egyptian hieroglyphics. Although we have a similar hound breed (Pharaoh hound) in modern times, this does not suggest that there is a continuous bloodline for this breed from ancient times (indeed the breed is much more recent in its origins). Many other breeds that have been developed in recent times can be traced back to particular historical periods or people.

The Englishman Robert Bakewell (1725-1795) is credited with the development of modern breeding practices in agriculture; he bred shire horses, small white pigs, longhorn cattle and Leicester sheep. At a time when it was unknown, the young Bakewell travelled extensively about the country, learning

agricultural techniques and studying the anatomy of animals. In 1760 he returned to work on his father's farm at Dishley, Leicestershire. Bakewell's innovation was to move away from the random breeding of stock to breeding 'in-and-in'. He separated male and female stock, only allowing mating between specific animals he selected. This process of 'inbreeding' allowed him to fix and exaggerate those traits he felt desirable.

Starting with old Leicestershire sheep, Bakewell bred the New Leicester, a big, fine-boned, barrel-bodied sheep with a good-quality fleece. The breed also had fatty forequarters, considered an important characteristic of sheep at that time. Bakewell also began hiring out his rams so that other farmers could improve their own stock. By the end of the 18th century the New Leicester had interbred with almost all other types of sheep, but it never replaced them. In 1783 Bakewell established the 'Dishley Society' to protect the purity of his stock. Matthew and George Culley were friends of Bakewell, and established a flock of New Leicesters in Northumberland, northern England, in 1767. Isolation from southern breeders meant that the Culleys interbred with local Teeswater sheep to produce the Border Leicester, which was recognized as a breed by the Highland and Agricultural Society in 1869. A breed society and flock book were established in 1898 in Edinburgh. Since 1850 the sale of crossbred sheep (Border Leicesters crossed with Cheviot or Blackface sheep) has been very important in British agriculture. The Border Leicester is still used to pass on large litter size and rapid growth in the progeny.

The process of breed differentiation has distinct steps. First, a type of animal is defined that is more useful and desirable than the ordinary type, but it is not differentiated in pedigree. This distinction may reflect recognition of a cline or the development of a **mutation**. Secondly, some of the best animals of that type are gathered into one or a few herds, which then cease to introduce much outside genetics. This population then undergoes **inbreeding** so that the animals become distinct from other animals in other captive populations. If this process is successful then the breed becomes more popular and more herds are established from the original inbred population. Marketing of the breed is crucial in becoming accepted and expanding its numbers. Once the breed becomes numerous, a herd book or studbook is established to record the numerous pedigrees. Finally, a breed society is formed to safeguard the breed and to advance the interest of the breeders.

There are around 5000 recognized breeds of domesticated herbivores around the world. For example, there are almost 1400 sheep breeds and almost 1300 cattle breeds, although there are only just over 100 breeds of ass. Not all breeds are thriving, because worldwide just over 700 breeds are considered extinct and a further 845 breeds are considered to be rare. Interest in old breeds of livestock remains high because of the historical value of these animals. However, breed differentiation provides genetic variability within the population of any species as a whole. Loss of any breed leads to a reduction in the genetic pool for the species. Maintenance of ancient breed types is critical to ensure that animals that are genetically relatively close to the wild progenitor are available for modern breeding programmes.

Breed societies

Breed societies are formed by animal stock-keepers for farmed, companion and sporting animals to promote the **breed** and to help ensure its survival and development. These societies in the UK and former colonies have an important influence on the development of a breed, as they set the 'breed standard' by which animals are judged. The breed standard in the past has sometimes been to the detriment of the individual animals concerned, as the standard tends to concentrate on the appearance of an animal rather than its function and fitness (in a Darwinian sense).

(DBM)

Breeding

The term 'breeding' is associated with the propagation of a particular species. However, the term is extremely broad and may refer to any number of aspects of the process of sexual **reproduction**. For example, breeding may refer to the behaviours associated with courtship and the act of copulation or the physiology associated with reproduction. It may or may not also refer to the behaviours associated with the production of the offspring, including 'brooding', the old English term from which breeding is derived, and **gestation**. Alternatively, breeding may refer to a controlled process in which individuals are selectively paired to produce offspring with a particular characteristic. Here, breeding will be discussed within the context of breeding in the wild, **captive breeding** and special scenarios associated with captive breeding.

Breeding in the wild

From an evolutionary perspective, the goal of breeding individuals in the wild is to maximize their genetic contribution to future generations. In order to accomplish this goal each species has evolved a series of complex **signals** and behaviours to identify individuals that are ready to reproduce and to help individuals identify receptive mates. Because of the relatively low physiological costs of reproduction for males of most species, males tend to seek to reproduce as rapidly and

P.70

as often as possible. Thus, they seek signals of readiness of a female to breed. These signals may include specific odours or behaviours that are influenced by hormone levels. These odours may be detected in the **urine** or faeces or from the anogenital regions of the female. The **flehmen** response seen in many mammalian species is thought to be a behaviour used to determine sexual readiness in females. Behavioural signals of readiness to breed include postures or particular combinations of behaviours that indicate that a female is prepared to mate, such as presenting for copulation. Generally, once males ascertain that a female may be physiologically ready to mate they begin courtship and attempts to copulate.

Alternatively, because of the high physiological costs associated with reproduction, females will often be selective in determining a male with which to mate. Given the costs and physiological constraints, females seek to determine whether they are getting the best male genes possible. As such, females tend to be selective and seek out certain characteristics in a mate. Females tend to seek out males that are physically robust, can provide adequate food, protection or living conditions, are socially dominant or whatever characteristics are most important, depending on the natural history of the species. Males may hold territories or physically clash with other males as a means of proving their worth; they may build nests or dens and they may engage in elaborate courtship displays to attract females. The idea is that by rating well on the required signal, a male can show his value relating to characteristics that are important to the species. Females use these signals, dependent on the criteria appropriate for their species, when selecting a mate.

Both the signals to the opposite sex and the actual act of copulation are important components of breeding. However, there are other components to breeding in some species. Egg-laying species may sit

on the eggs to keep them warm or defend them from potential predators. For example, after copulation females of certain hornbill species nest in excavated cavities in trees. The female and her mate seal her inside the tree cavity with a combination of mud, food and faeces. A small hole is left open through which the male feeds her while she sits on the eggs. Once the eggs hatch the female breaks out and they reseal the tree cavity. This behaviour enables both the male and female to feed the chicks until the young are old enough to fledge. While this strategy helps to prevent egg and chick loss due to predators, it requires a great deal of investment from both parents. In this case, breeding involves much more than simple mate selection and copulation: it involves elaborate, coordinated behaviours of both the male and the female.

The principle of natural selection drives reproductive behaviours and cues. Individuals that are able to successfully produce more offspring spread a greater percentage of their genes into the population. Those behaviours and strategies with a genetic basis that are successful will become more prevalent in future generations because they comprise a greater percentage of the genes in the population. It is important to note that no single breeding strategy works for all species. The appropriate breeding signals and behaviours have developed over long periods of time and exist in response to the ecological pressures that face the individual species. As a result, each species, even closely related ones, may have developed different strategies and signals based on the techniques that have proved successful in the past.

Breeding in captivity

In contrast to breeding in the wild, where females and males make selections of appropriate mates based on their signals of worth, and those strategies, if effective, are passed on to future generations, breeding of animals in captivity often involves human intervention. Breeding of animals in a captive setting is often termed artificial selection, because it involves the human selection of animals to reproduce, not what would actually be successful according to the criteria of natural selection. Captive breedings are chosen to meet one of two criteria for artificial selection. The first selection type is based on the human desire to obtain some particular physical or behavioural characteristic in the offspring. For example, livestock have been bred to produce the largest individuals because this tends to make the animals more valuable for the amount of meat that they can provide. Animals such as dairy cows are often bred to maximize milk production, and fibre-producing animals such as alpaca are bred to produce certain colours or quality of fibre. Domestic animals may be bred for a certain behavioural characteristic such as chasing rodents, as in terriers, or retrieving hunted waterfowl, as in retrievers. Domestic animals are often bred for temperament, as the most easily handled animals are often bred to create offspring that are calm around people.

The goal of this type of artificial selection is to make a certain trait or characteristic more prevalent in the offspring. This may even involve a breeding process called line breeding, in which offspring are bred to their relatives to further increase the possibility of a desirable characteristic in future generations. This process of artificial selection greatly impacts the genetics of the species, as animals with less desirable traits (from the human perspective) are not provided with the opportunity to reproduce and, as a result, these traits become less common or may disappear from the captive population. Additionally, certain traits that occur at a variable level in the normal population become set in the captive population. That is, all individuals have that trait because there are no other genetic alternatives in the gene pool.

Another technique for breeding animals in captivity involves the selective breeding of individuals to maintain genetic diversity, but again without concern for which traits would be most adaptive in the wild condition. For example, in zoos and aquariums around the world, exotic animals are bred to maintain the largest variability of genes possible. By maintaining a greater diversity of genes, zoos and aquariums seek to avoid selectively breeding out characteristics that we currently feel are undesirable. The genetic population is nearer the naturally occurring genetic variability in the population than in populations that are bred for a certain characteristic. This effort is designed to prevent **inbreeding** and **genetic bottlenecks**, which may cause physical problems in later years. Additionally, it makes the genetic stock as

similar as possible to the animals in the wild, given the chance that animals are able to be reintroduced or transferred to another region of the world.

Currently, there are zoo and aquarium associations in regions all over the world. Each organization attempts to manage the genetic diversity of individual species by regularly

P.71

reviewing its population and conducting genetic, demographic and logistic analyses to produce a plan for individual breeding recommendations. The member zoos and aquariums of these organizations agree to breed or not breed their animals according to these recommendations in an effort to preserve long-term genetic diversity of the species and ensure their long-term success in captivity.

Breeding challenges in captivity

It is important to note the challenges associated with both captive breeding strategies. When animals are bred for a single characteristic there are often unwanted, unforeseen side effects. For example, extreme breeding for size in broiler chickens and other poultry may result in animals that cannot fly or may have difficulty supporting their weight. Additionally, purebred dogs may have physical ailments, such as bulldogs and pugs, which have been bred for shorter muzzles, and often have difficulty in breathing. Temperament characteristics may also be associated with physical characteristics. In attempts to breed a tamer fox, scientists found that the resulting offspring differed in coloration, tail placement and ear shape. In a sense, the new foxes did not look like foxes. Line breeding for a particular characteristic may result in a genetic composition that is quite different from the original species and may have many other characteristics.

Breeding for genetic diversity also has its challenges. When a single male is selected for a female that usually would select her own mate from many choices, it is always possible that the two selected individuals will not reproduce. Lack of reproduction in a particular pair causes many challenges when maintenance of genetic diversity is the goal. Zoos and aquariums often deal with small population sizes, and the amount of genetic diversity available is already limited. If particular individuals do not reproduce, they can have no genetic contribution to future generations and it makes it more difficult to maintain the genetic diversity goals into the future. Additionally, if some individuals of a species breed well while others do not, animal managers are potentially selecting for individuals that breed well within the captive environment, which may lead to the same problems associated with selectively breeding for a particular trait.

Finally, breeding for genetic diversity creates serious logistical challenges. As opposed to instances of line breeding in which it may be desirable for a single male to breed with dozens of females and their offspring because he has a desirable set of characteristics, breeding for genetic diversity calls for no particular individual to have an overabundance of offspring. This means that animals need to be moved from group to group or from institution to institution on a regular basis to produce the most genetically diverse pairings and offspring. This strategy requires that animals must be transported between institutions and they must be introduced to new groups or individuals. This is resource consuming and can be problematic when certain animals do not get along and will not reproduce.

Artificial breeding

One of the techniques that has been recently explored to help deal with some of the challenges associated with captive breeding is artificial breeding. Artificial breeding often involves the **artificial insemination** of females or embryo transfer. This process has been used in a number of zoo-housed animals, most notably elephants.

Artificial breeding is advantageous in a zoo setting because the challenges associated with frequently moving an animal are eliminated. This is particularly important when animals are susceptible to

transportation stress or when they are extremely difficult or dangerous to move. The ability to artificially inseminate elephants eliminates the need for long trips in a truck for the elephants, and allows institutions that do not have facilities for holding a bull elephant to be able to successfully breed their female elephants. Another potential advantage of artificial breeding is that sexual sorting of sperm can be carried out prior to the insemination technique. This can be helpful for species in which there is a large number of solitary males that are surplus to the reproductive population, such as gorillas or elephants. In these cases, male offspring are unlikely to be able to live in a social group after they reach reproductive maturity and, as a result, females are more desirable within the population for breeding purposes. While this option has been suggested for use within zoos and aquariums, it has yet to be perfected and tested on a large scale.

Artificial breeding within the captive context does have many advantages, but there are also some disadvantages. Chief among these is the fact that the technology associated with artificial insemination is quite expensive, and the process of collecting semen samples and the insemination process can be quite labour intensive. Many zoos and aquariums do not possess the funds to be able to invest in such a technology and, at the current time, it is cost prohibitive. However, as technology continues to move forward, it is not unlikely that we will begin to see more and more artificial breeding techniques being employed in the captive animal setting.

Buddhism

Buddhism has a strong position in Asia, but there is also a growing interest in Western cultures, partly thanks to its view of human relation to nature. Buddhism is perceived as building on a deeper understanding of human dependence on, and intimate relation to, animals than found in mainstream Judaeo-Christianity. Several central elements in Buddhism contribute to this. One fundament is the continuity of all life forms, expressed in the idea of reincarnation, i.e. every sentient being's rebirth in different life forms. In the popular Jataka stories (about Buddha's previous reincarnations), relations between animals and between animals and humans are important. An enlightened Buddhist will 'know' his or her previous

P.72

lives, but also without this specific knowledge a Buddhist regards an animal as a possible future human, or

even a former human. Tightly related to this is a second element, the idea of karma, i.e. that we will experience the effects of all our intentions in the present and the next life. A third element more explicitly influencing the human-animal relationship is the ideal of non-violence (ahimsa). This is expressed in the first of the Five Precepts 'Ye shall slay no living thing'. A fourth element is action guiding, the ideal of compassion, understood as the primary ethical value. On these grounds Buddha not only objected to animal sacrifice, but showed animals respect. These core elements are valuable incentives to treat animals well, or at least not intentionally to inflict harm.

According to the Lotus sutra, central in Mahayana Buddhism, animals also have Buddha nature, and can thus be fully enlightened. However, influential lines of Buddhism also include clear elements of hierarchy between humans and other animals. According to this only a human can attain enlightenment, and every human is more valuable than any other animal since their physical nature is a manifestation of moral status, and 'human nature is itself a product of moral evaluation' (Keown, 1995). In practice, neither the non-harming principle nor compassion has been strong enough to prevent captivity or instrumentalization of animals in Buddhist countries. Waldau (2002) concludes that both Buddhist ideals and practice to some extent are hierarchical, or speciesist. This tenet runs parallel to **Christianity**.

Buffalo

The African buffalo (*Syncerus caffer*) and the Asian buffalo (*Bubalus arnee*) are similar in appearance, both having typically angular horns in section compared with the circular or oval shape of the cattle horn. The former is a larger animal (examples exceed 1000 kg liveweight), with more massive horns that are joined at the base where they are heavily thickened. In addition, the African buffalo has not been successfully domesticated (though individual animals have been tamed). There are wild Asian buffaloes extant, but the Indian wild buffalo (*Bubalus arnee*) is the only one to have been domesticated, the domesticated species being named *Bubalus bubalis*. The largest of the domesticated buffalo weigh around 600 kg. The earliest evidence of **domestication** is derived from representations of tame buffalo in artefacts from around 2500 BC in Mesopotamia and the Indus valley. The wild Asian buffalo may have extended through Europe and Asia in the Pleistocene period, but the buffalo in Europe today was reintroduced as a domesticated species.

Their arrival as a domesticated animal has been attributed by various authors to Arab conquest, returning Crusaders or as gifts from Arab leaders to European kings. By whatever means, domesticated buffalo were to be found in Europe - in Italy and the Balkan states - by the end of the 13th century.

Buffalo are adapted to an environment that is warm and wet, though they are not particularly heat tolerant. The buffalo includes shade seeking and wallowing among behavioural strategies to combat **heat stress**. As they have few sweat glands, buffalo lose relatively little heat through sweating and, if they are denied access to shade or wallow resources, they can quickly become heat stressed in hot conditions. They will seek out water, but it is unclear whether allowing buffalo the opportunity to wallow, where it is often denied, is necessary for their optimal production in European conditions. If given the opportunity buffalo will spend long periods wallowing, but wallowing animals have been observed to graze for longer periods than those in the absence of wallows. The management of wallowing areas needs to be carefully regulated: if the water is not continually flowing, excreta and other waste will soon build up, compromising the welfare of the animals using it on health grounds. Whatever the breed, time of day or season, the body temperature of buffalo is always lower than that of other cattle, and this difference is greatest in the early morning or in the cool season, suggesting that their welfare may be more compromised than cattle in a cold environment.

The domesticated buffalo will breed with neither the African buffalo nor cattle to produce offspring (though copulation has been observed). They are broadly classified into river and swamp breeds, with river buffalo having higher milk yields. Between-breed hybridization has successfully bred productive animals.

The purposes of keeping buffalo worldwide include milk, meat, hide, work and entertainment/ritual. Milk yields average 2000 kg per lactation (commonly around 305 days). This low quantity compared with cattle is in part compensated for by the higher fat content (up to 10%), which, it is claimed, has a lower level of cholesterol. Individuals are productive for up to 20 lactations. Additionally, buffalo milk has less of an allergenic effect, allowing consumption by humans with dairy allergies. The milk is creamy in taste and has a pure white colour - the buffalo, unlike the cow, does not secrete beta-carotene in the milk. Irrespective of the diet, beta-carotene is converted more efficiently into vitamin A, which is colourless. Buffalo milk is used for the production of mozzarella-type cheese.

Meat is generally regarded as a by-product at the end of the dairy animal's life, and it can be of rather poor quality. However, if the buffalo is raised as a meat animal the product is similar in quality to beef. With a comparatively lower fat content than beef, and a higher protein content, there is a scope for development of buffalo meat production. They are reported to have good forage conversion rates and infrequent calving problems.

The hide is valued as it is not damaged by warble fly larvae, which cause widespread damage worldwide to the hides of cattle. It is used for the production of heavy leather articles such as shoes, belts and saddles. Their horns can be used to produce handicraft products on a cottage industry scale.

Both males and females are used for work - in the fields (ploughing and harrowing) and for threshing, milling, raising water from wells, transporting material by cart or by pack and for riding. Although less swift than cattle, they have greater

P.73

muscular power and are particularly preferred for tasks such as ploughing heavy soils. The domesticated buffalo (*B. bubalis*) is a docile animal that is easily trained.

Buffalo have entertainment value and, in the UK, as an exotic experience: animal producers have added value by opening to the public and training animals to pull carts for rides, and so on. Buffalo racing is a sport in Indonesia and the Philippines, and entire males are kept as fighting animals these are pushing matches, but may result in fatalities. The buffalo is also important in religious ceremonies and for ritual

slaughter (making the blood of a buffalo flow is believed to increase rainfall and the rice harvest in parts of Indonesia, and decapitation with one blow of the khukri knife is believed to bring the promise of good harvest to some in Nepal).

Buffalo faeces are prized as a fertilizer in Europe and elsewhere, as a flooring medium and, when mixed with straw and chaff, a fuel. The last is particularly important in regions with scarce access to fuel.

Bull-baiting

Baiting refers to the harassment of one animal by another and is a form of public entertainment that can be traced back thousands of years. In bull-baiting, the bull is typically tied with a 15-foot (5-m) rope around the base of its horns and is tethered to a stake in the middle of an arena. Trained dogs, generally bulldogs, surround the bull and are released one at a time to bait the bull. The dogs are taught to stay low and avoid the horns while trying to attack the bull, usually by seizing the bull by the nose and holding on in an attempt to immobilize it. This practice has long been criticized as unethical and was prohibited in the UK by an Act of Parliament in 1835. There are a number of animal welfare concerns associated with bull-baiting, including stress and injury of the bulls, stress and injury to the dogs and even injury to members of the audience and dog handlers. While bull-baiting is illegal in most developed countries, it continues as part of a cultural tradition in others and may still occur in areas where it is banned.

Buller-steer syndrome

Buller-steer syndrome is a behavioural problem characterized by repeated and persistent mounting of one steer (castrated bovines), termed the buller, usually by a group of steers, termed riders. The frequency of mounting can be very high, in some cases exceeding 60 mounts per hour, resulting in stress and exhaustion with associated minor or even major traumatic injury and, in extreme cases, **death** of the buller. The syndrome is most prevalent among feedlot steers, where the overall incidence has been reported to be between 2 and 4%, a level sufficient to raise significant economic and welfare concerns within the industry; it may also be occasionally observed with pasture-raised steers.

There has been some discussion as to whether this behaviour is initiated by the buller standing passively, or even in some way soliciting mounting by the riders, or whether it is the riders that target a particular steer for mounting. Removal of the buller animal has generally been seen to alleviate the problem and the attention of the riders is not automatically refocused on a new buller, which would seem to indicate that it is the buller that is the initiating factor. However, observational studies have shown that the majority of bullers, rather than standing voluntarily, do actively seek to avoid mounting by riders, suggesting that it may be the riders that are the initiators.

A number of variables have been investigated as possible causative factors for the syndrome, and there is evidence for both increased stocking density and the use of anabolic steroids such as growth promoters having an effect on incidence of the behaviour, while a range of other variables, including seasonal and environmental factors and entry weights, has been shown to play a much less clear-cut role. There is however, probably a relationship between the incidence of the syndrome and the establishment and maintenance of social hierarchies (**see: Hierarchy**), with an increased appearance of the behaviour when new hierarchies are being established or existing ones are disrupted by the movement of steers.

Bullfighting

Bullfighting has its origins in the ancient Greek and Roman practice of bull sacrifice, but was introduced into Spain by the Moors, who established bullfights in the ancient Roman amphitheatres of Andalusia. The practice saw a resurgence in popularity in the 1970s and 1980s, despite mounting criticism from animal **welfare** activists. It is now legalized within the European Union by special exemption from **slaughter** regulations on the grounds of cultural heritage. It occurs mainly in the Iberian peninsula, south-west France and South America, with approximately 10,000 bulls killed annually. It has its greatest following in Spain, where there are just over 1000 bullrings hosting about 1500 fights per year, killing approximately 4000 bulls. There are also a number of practice fights with animals that are not thought suitable for a major event. A major industry has developed to support the sport, with approximately 200,000 people employed in rearing bulls, maintaining the bullrings, etc.

Over the years the practice has developed into a more elaborate spectacle, with glittering costumes and large prizes for successful matadors, and much celebration and fiesta. However, many young people have little interest in bullfighting and there is concern that the close-up pictures of the fight, and in particular the **death** of the bull, on television are bad for the moral upbringing of children and will desensitize them to violence. Children under 14 years of age are banned from attending fights in some regions of Spain, and other regions have banned bullfighting altogether.

The bullfight differs from ritual slaughter of animals, or even **cock-fighting** or fox **hunting**, because the bullfighters or matadors face considerable danger when fighting the animals. The contest between man and animal has been romanticized by leading authors, such as Ernest Hemingway, and artists, such as Pablo Picasso. The animals are bred to be brave and to respond rapidly and vehemently to the challenge by humans. Their courage is exemplified by a willingness to charge a man on horseback. The animals must be so reactive to provocation that they charge up to the point of death, and they must not cry out or retreat when wounded.

The breeding programme has led to the development of animals that are hypersensitive and nervous, quite different

P.74

from cattle that are used for milk production, which have been bred for docility. The animals for fighting are selected at an early age by challenging them to assess their levels of aggression. They are kept on extensive pasturelands, so that they have little contact with humans, and their reaction to the matadors in the fight then appears all the more valiant if they have not been subjugated by humans before. Females are selected for breeding by testing their charge at horses when provoked with lances jabbed into their backs. For the fight the bulls must be lean, strong and not too heavy, or their charge is slow. To achieve this they mainly graze on natural pasture with little supplementation, to prevent them becoming obese. They are weaned at about 8 months and branded. Their slow growth makes them mature late and, typically, they fight at 4 years of age, by which time they weigh around 600 kg. They have little contact with humans and there are no practice fights before they enter the ring.

The bull must come to the fight well nourished, to give him enough energy to be able to charge with vigour to the last. He should be kept under as little **stress** as possible, otherwise his performance will suffer. A veterinarian is present at each fight and has to certify the animal's welfare before the fight.

There are regional variations to the bullfight, with a fight to the death being the norm in Spain and South America but not in France or Portugal, where the bull is professionally slaughtered immediately after the event. After the extreme stress suffered by bulls during the fight, the best course of action for the bull on

welfare grounds is slaughter as soon as possible, regardless of whether it is in front of a crowd of spectators.

Each fight lasts for about 20 min, with four to six bulls per event. The matador normally fights two bulls at each event. He has assistance from two picadors - men carrying long pikes with 10 cm steel tips - and three bandilleros - men on horseback with decorated wooden sticks that end in a barbed harpoon. Initially, the picadors thrust the pikes two or three times into the bull's shoulder muscle as he charges, to weaken his tossing ability. Next, the bandilleros jab up to eight of their harpoons into the bull's back to further weaken it. A 'good' bull does not cry out when they are inserted and indeed shows no signs of pain throughout the event. Then the matador taunts the bull by tempting it to charge a large piece of cloth, coloured fuchsia and yellow, held outside his body. This stimulates the bull with its movement and takes its attention away from the matador. This taunting continues until the matador has complete control of the charging bull, which may take about 20 charges. During this period the bull may also charge the matador. Then, with his sword in his right hand, he attracts a final charge at a small bright red cape held directly in front of his body with his left hand. It seems likely that the bright red colour and the positioning of this cape are designed to extract the last vestiges of aggression in the bull. Red is commonly found to incite arousal in other species and this universal phenomenon is used to good effect by the bullfighters. As the bull charges, the sword is plunged between the bull's shoulder blades and, if correctly positioned, will cause instant collapse and death. If the bull fails to die, the matador will lance the neck with a short sword, causing immediate death. A bull is considered to be more courageous and honourable if it dies with its mouth closed.

Bushmeat

In Africa, forest is often referred to as 'the bush'; wildlife and meat derived from forests is called 'bushmeat' (in French: *viande de brousse*). The term applies to all wildlife species including those that are threatened or endangered - that are hunted for their meat. The rapid expansion of **hunting** for the commercial sale of wildlife meat has become the most immediate threat to the future of wildlife in the Congo Basin, and has already resulted in widespread local **extinctions** throughout West Africa (BCTF, 2000).

Wildlife has been hunted for food ever since humans first evolved, and is still viewed as a resource 'free' for the taking in many areas. Today in Africa, bushmeat continues to be an economically important food and trade item for thousands of poor rural and urban families. Bushmeat has also become a status symbol for urban elites trying to retain cultural links to 'the village', often commanding extremely high prices in city restaurants. The immediate loss of wildlife and the secondary loss of many plant species jeopardize the function and stability of natural habitats - including both forests and savannahs threatening the long-term survival of ecosystems and the people dependent upon them.

The bushmeat crisis refers to the current unsustainable, illegal, commercial trade in wildlife in Central Africa and around the world. Problematic bushmeat hunting may take place with illegal methods (such as wire snares that capture and kill indiscriminately), may injure or kill protected species, may take place in protected areas or may remove too many individuals from a population (**see: Wildlife management**). Logging operations deep in the forest often transport hunters and traders to the forest and carry wildlife to urban markets. This commercial trade is markedly different from subsistence hunting. Subsistence bushmeat hunting may be sustainable where human population densities are very low and markets are inaccessible (Robinson and Bennett, 2000). However, growing human populations with few economic

alternatives and little opposition from law enforcement officers will continue to demand bushmeat, both for its protein and for its cultural value.

The health of humans, wildlife and domestic animals are closely linked in the bushmeat trade, and disease transmission between species has been documented. Particularly distressing is the multiple transmission of immunodeficiency viruses between primates and humans: more than 26 species of primates carry a variety of simian immunodeficiency virus (SIV) (Wolfe *et al.*, 2000). Ebola, which results in death for approximately 80% of those who contract it, equally affects humans and great ape populations, and may be passed from one species to another in the preparation of bushmeat.

Though deforestation has an obvious impact on wildlife dependent on these habitats, hunting constitutes a comparable threat to the ecosystem itself, in that it often results in Empty Forest Syndrome: a forest filled with trees, but with few, if any, large animals (Redford, 1992). Such forests will, over the long term, suffer dramatic changes in structure and composition as the wildlife responsible for dispersing seeds is lost through overhunting.

The bushmeat crisis is a global problem, with effects on people, wildlife and landscapes around the world. In Central Africa, estimates suggest that 30 million people consume

P.75

2.5 million t of meat per year (Wilkie and Carpenter, 1999). In East and southern Africa bushmeat is a growing problem, and is frequently turned to during periods of economic hardship or when fast cash is needed. West Africa's wildlife has already been hunted to depletion: the main species available in today's West African bushmeat trade are rodents and small antelope.

The wildlife trade in other areas of the world is also of great concern. Numerous species of fish have been overharvested around the world to satisfy an unsustainable demand; overfishing off the coast of West Africa has been linked to increased demand for bushmeat in the region. In addition, nearly 60% of the world's population now lives in Asia; China's growing middle class drives an enormous demand for wildlife products used in medicine, food and cultural ornamentation. The Asian turtle trade is so great that it is measured in tonnes rather than in numbers of individuals.

From a biodiversity-conservation perspective, the commercial-scale bushmeat trade threatens the survival of many species, including **great apes, elephants**, antelopes and others, as well as the ecosystems in which they live. From a human development perspective, the commercial bushmeat trade threatens to remove a needed source of protein from rural, poor human communities that depend on bushmeat as their primary protein source. While momentum is building to legalize the commercial bushmeat trade in Central African countries, it is highly unlikely that a legal trade would be ecologically sustainable, nor would it alleviate poverty. A recent analysis of bushmeat data collected in Gabon concluded that implementation of a legal, sustainable bushmeat trade would be far too costly to regulate (not even a 25% tax on bushmeat sales would cover the costs for law enforcement and tax collection) (Wilkie *et al.*, 2006).

Using data from throughout Central Africa, Fa *et al.* (2003) concluded that maintaining current bushmeat offtake levels without protein alternatives would result in a reduction of 81% in bushmeat protein supply in less than 50 years. Four out of the five countries studied do not currently produce sufficient non-bushmeat protein to ensure that their citizens consume the minimum daily requirement of protein; if bushmeat off-take suddenly decreased to sustainable levels, only Gabon would be able to maintain its population's protein demands (Fa *et al.*, 2003). Clearly, development of alternative livelihood (protein as well as income) strategies is needed immediately to maintain both human and wildlife populations.

There is no panacea solution to the bushmeat crisis. Different countries, ecosystems, cultural groups, wildlife populations and economic systems require different approaches to assure the long-term security of biodiversity and the health of human populations. An example of an integrated approach to solving the bushmeat crisis is found in a collaboration between the government of the Republic of Congo, the

Congolaise Industrielle des Bois logging company and the Wildlife Conservation Society in the Northern Republic of Congo. These stakeholders have teamed up to assure appropriate policy development, adequate law enforcement and capacity building, hunting regulations (including strict enforcement of zones, methods and species), providing alternative protein and income sources, awareness building and collaboration with the local community, and continued monitoring and evaluation (Bennett *et al.*, 2005).

Conservation professionals agreed in 1999 to create the Bushmeat Crisis Task Force (BCTF) to fulfil a mission of building a public, professional and government constituency aimed at identifying and supporting solutions that effectively respond to the bushmeat crisis in Africa and around the world. The BCTF goals include effective information management targeted at engaging key decision makers, facilitating education and training and raising public awareness. Resources for key decision makers, educators, journalists, scientists, communities, students and the public are available at <http://www.bushmeat.org>.

Caecotrophy (cecotrophy)

Caecotrophy is a particular form of **cophrophagia** (faeces eating), seen in certain species of hind gut-fermenting herbivores such as lagomorphs (including **rabbits**), whereby they eat faeces directly from the anus. Since these species digest fibre in an expansive caecal region, they have less opportunity to absorb some of the nutrients before their elimination. By re-ingesting these initial faecal pellets (caecotrophs), digestion is improved. In captive rabbits the use of surgical collars to prevent self-injury, e.g. following castration, can prevent this behaviour by inhibiting neck flexion and result in serious malnutrition if prolonged.

(DSM)

Camelids - South American

Basic biology

There are six types of Camelids: the domesticated; the onehumped dromedary of southern Asia and North Africa; the two-humped Bactrian camel, which is still found wild in the Mongolian steppes; the domesticated llama and alpaca; and the wild guanaco and vicuña found in South America (see Table C.1). The llama is among the world's oldest domestic animals. While the llama is used mostly as a beast of burden in the Andes of Peru, Bolivia, Chile and Argentina, carrying things for the native herdsmen, it also provides the herdsmen with meat, wool, hides for shelter, manure pellets for fuel and was used as a sacrificial offering to their gods. In North America, Europe and Australia llamas are used as pet animals, backpacking for trekking expeditions, tourism, cart pulling, public relations, showing, parades and fairs, guardians of other livestock (such as sheep), golf caddies, therapy and, less importantly, production herds (for their wool).

Llamas are the largest domesticated members of the South American camelids, four species that have been the product of a long evolutionary history, marked by an affinity towards arid and semi-arid environmental conditions and the development of a unique series of characteristics. A llama's lifespan is about 15-18 years; however, they can live longer with care. An adult llama weighs between 100 and 150 kg. Their stomach anatomy consists of three compartments; they possess high-altitude physiology adaptations that allow them to live up to 4600 m above sea level - such as elliptical blood cells and locomotory traits suitable for walking in arid environments (moveable toe pads). The split upper lip, the long, curved neck, lack of tensor skin between thigh and body are all, together with the fine fibre fleece, adapted for **thermoregulation** in extremes of cold and hot. Llamas are seasonal breeders and mate lying down on their chest - copulation last 10-20 min and induces ovulation. Gestation lasts 11 months and the mother gives birth to a single offspring in a standing position. Llamas neither lick the newborn nor eat the afterbirth; the newborn is active and follows its mother within 15-30 min of birth. The female comes into heat again 24 h after birth, but usually does not mate for 2 weeks following recovery of the uterus. The

four South American camelids can interbreed, producing fertile offspring; they all have the same chromosome number ($n = 74$).

Table C.1. Camelids of South America.

Name	Order	Family	Genus	Species	Habitat
Llama	Artiodactyla	Camelidae	<i>Lama</i>	<i>Lama glama</i> Linnaeus 1758	Central Andes of Peru, W. Bolivia, N.E. Chile, N.W. Argentina
Guanaco	Artiodactyla	Camelidae	<i>Lama</i>	<i>Lama guanicoe</i> Muller 1776	Andean Foothills of Peru, Chile, Argentina, Patagonia
Alpaca	Artiodactyla	Camelidae	<i>Vicugna</i>	<i>Vicugna pacos</i> Linnaeus 1758	Central Andes Peru to W. Bolivia
Vicuña	Artiodactyla	Camelidae	<i>Vicugna</i>	<i>Vicugna vicugna</i> Molina 1758	High Andes of central Peru, W. Bolivia, N.E. Chile, N.W. Argentina

Evolution

The llama's ancestors originated in the Eocene, approximately 40-45 million YBP, in North America. *Hemiauchenia*, which originated in mid-Miocene, already presented many of the characteristics of the true camelids. This genus began spreading towards more southerly latitudes of North America. During the Pleistocene (3 million YBP), the formation of the Panama isthmus formed, allowing *Hemiauchenia* to reach and thrive in South America. *Hemiauchenia* evolved into *Paleolama* and *Lama* approximately 2 million YBP in the Andean Zone of South America. Both genera showed a reduction in the length of their extremities and dental changes, implying better adaptation to harsh grassland, accompanied by an increase in the level of browsing in the diet. In terms of comparison, the habitat of *Hemiauchenia*

consisted of flat terrain with a grazing diet while the habitat of *Paleolama* was mountainous, favouring browsing and grazing behaviour. The genus *Vicugna* supposedly originated during the same time.

P.78

Towards the end of the Pleistocene, between 10,000 and 12,000 years ago both *Paleolama* and *Hemiauchenia* genera suffered extinction, as did the rest of the megafauna that had settled in South America. *Lama* and *Vicugna* have persisted until the present, being represented by two wild species, the guanaco and vicuña, whereas llamas and alpacas originated from the domestication of their wild counterparts, processes that began approximately 7000 years ago. Because the process of domestication is closely related to the cultural action of man and their livestock, the distribution and radiation of llamas and alpacas occurred in the Altiplano zones of the central Andes.

Domesticated camelids

The llama is the largest of the South American camelids, with a slender shape, and may be found in up to 50 different colours. The llama has elongated legs, neck and face, and may reach as high as 1.5-2.0 m from the ground to its head. Its long ears are erect and curve inward in a classic banana shape. There are two breeds of llama traditionally recognized - the woolier being called *Ch'aku* and that with less fibre on the neck and body known as *Q'ara*. Their fibre (technically it is 'fibre' and not 'wool') is less dense than in the alpaca, with an average diameter of 26 µm on the undercoat and 70 µm on the guard hair.

The alpaca presents two recognized breeds, the Huacaya and Suri. The alpaca is the primary South American camelid fibre producer of the Andean Highland.

The vicuña is the smallest of the Andean camelids and has the finest fibre coat, the overall colour of the soft woolly coat being ochre, light cinnamon or reddish brown, with the underparts, insides of the legs and underside of the head being a dirty white. Unique among living artiodactyls, the incisors of the vicuña grow throughout life. The guanaco has a similar silhouette to that of a llama, with a uniform coloration - a dark brown upper body, neck and limbs; whitish fibre on the underside of the neck and belly; and greyish to black face. The guanaco's fibre has a diameter of 18-24 µm.

Distribution and welfare aspects

Today there are approximately 21.5 million camelids in the world, with around 8 million in South America alone: llama, 3.7 million; alpaca, 3.3 million; guanaco, 875,000; vicuña, 250,000. Most alpacas and vicuñas are to be found in Perú, the majority of South American llamas are in Bolivia and nearly all the guanacos are in Argentina and Chile. Overall in South America the number of alpacas, vicuñas and guanacos is increasing due to the value of their fibre, whereas llama numbers are falling. In the USA and Canada there are an estimated 160,000-200,000 llamas and up to 60,000-90,000 alpacas.

People's attitudes towards llamas differ greatly between South America and North America, and this determines the kind of **welfare** problems that arise. Llamas comprise extensive herds grazing in open and poor grasslands with extreme temperature variation between day and night in the Andes. Poor, indigenous farmers had developed a traditional way of farming llamas even before the Inca empire and for more than 4000 years. Welfare problems such as freezing after shearing, predation, abandonment of crias (juveniles) and outbreaks of livestock diseases - such as enterotoxaemia, mange and rotavirus in crias - cause large mortalities and losses in Andean herds. Shearing also causes deep skin cuts and infections due to poor technique. In conclusion, **hunger** and freezing are the main animal welfare concerns in South American llamas. On the other hand, llama farming in North America faces problems of overfeeding, heat stress in humid and hot summers and behavioural problems in bottle-fed animals in close contact with humans. In addition, the isolation evidenced when llamas are kept as pets causes stress and abnormal behaviours.

Llamas and alpacas are becoming a new type of farm animal worldwide, and not simply the livestock of the traditional indigenous communities of the Andes. Herd practices and animal welfare recommendations should bear in mind their evolutionary adaptations to open and extreme environments moulded by cold weather and high altitude, and also the complex behavioural and physiological traits that make them a unique species.

(CB)

Cannibalism

Cannibalism occurs when one individual consumes all or part of another individual of the same species. Cannibalism can be found in nature and may occur for a number of reasons. For example, sexual cannibalism occurs when, within a species, a member of one sex kills a member of the opposite sex (usually the female kills the male) before, during or after copulation; this occurs primarily in insects. Another well-known form of cannibalism is filial cannibalism, where the offspring of a species are killed and consumed by adults of the same species. A common example of this occurs after a new male kills and replaces the dominant male of a harem.

Cannibalism is also found in animal production systems. However, this type of cannibalism does not appear to have an evolutionary basis and is often described as **abnormal** or problem behaviour. It is thought that unnatural, intensive conditions lead to **stress** responses and **frustration**, and this may lead to the cannibalism. For example, chickens commonly **feather peck**, which is considered an abnormal or **stereotypic behaviour**, when kept in production systems. Feathers are removed during the process, which can lead to bleeding that stimulates increased pecking and cannibalism. Similarly, pigs kept in intensive production systems may **tail bite**, that is, they chew and consume tissue and blood from another pig's tail. Cannibalism is an ongoing problem in animal production and, after one incident occurs, others may follow, leading to an outbreak. There is no definitive solution to the problem, but the addition of **enrichments** to the environment, separation of injured animals and removal of dead animals can help control the problem.

Outbreaks of Bovine Spongiform Encephalopathy (BSE) or mad cow disease are believed to be linked to the feeding of infected cattle as meat- and bonemeal back to normally herbivorous cattle. This has led to over 179,000 cattle becoming infected in the UK alone, with over 4.4 million cattle euthanized as a precaution.

Captive bolt

A handheld gun containing a metal bolt that is used in the slaughter of animals. It renders animals unconscious immediately, through either penetrating the skull or by having a percussive effect that causes

concussion and intracranial haemorrhage. The animal is subsequently killed by bleeding it out through severing the large blood vessels in the neck and upper part of the chest before it can regain consciousness.

(DBM)

Captive breeding programmes

Captive breeding refers to the managed propagation of wild animals in captivity, namely **zoos** and **conservation centres**. Systematic breeding programmes were established to create self-sustaining captive populations to prevent species extinctions in the wild. The long-term captive management of endangered species provides the time during which those factors leading to species extinction can be determined and hopefully ameliorated.

Many domesticated animals are selectively bred for desirable traits. For example, Robert Bakewell (1725-1795) bred the largest of his cattle together and, after a number of years, created a cow that had doubled in size (from 370 to 840 lb, or 815 to 1850 kg). Conversely, captive breeding programmes are set up to maximize genetic diversity and avoid **inbreeding**, thus avoiding selection for or against specific (desirable/undesirable) traits. This can be achieved through even production of offspring from all founders (wild-caught animals) and subsequent offspring, so that genetic integrity remains and is maintained within the captive population. The advantage associated with maintaining genetically diverse captive populations is that these will reduce the likelihood of animals becoming adapted to captivity and so they will represent their wild counterparts, thus improving the likelihood of surviving **reintroduction**, the long-term goal of much captive breeding. It also reduces the likelihood of inbreeding.

Genetic selection occurs due to environmental pressures, both in the wild and in captivity, and results in animals that are able to survive and breed in their surroundings. It is difficult to avoid selection in animals in their temporary captive surroundings, as they may live in zoos for several generations. If wild animals do not breed in zoos their genetic contribution to the next generation will be lost, unless they have kin within the population. In these circumstances, against our best efforts, selection of animals that are able to breed in a captive environment occurs.

Another potential problem in captive breeding occurs when related animals are bred together - an activity employed to achieve 'pure blood' individuals, for example in pedigree dogs and cats. This process is called inbreeding and, although it results in animals that have some desirable qualities, as determined by the breeder, it is also associated with a range of problems (see: **Mutations**). Inbred animals have been found to be more susceptible to disease, and thus increased morbidity, and have physical abnormalities, reduced longevity and reproductive difficulties.

European bison were the first species to be systematically managed to prevent **extinction**. Heinz Heck managed the population and published his studbook in 1932. Studbooks are central to the management and propagation of many animals in captivity. Within the zoo community studbooks contain information about the population (living, historical and projected) and individuals (their age, location, genetic representation within the population, inbreeding status). Basic studbooks provide information on the number of births, deaths and transfers between zoos that occur yearly. Analysis of these data can provide important information about the demographic and genetic status of the population.

A key role for zoo associations worldwide is the coordinated captive breeding of animals. Captive breeding programmes

P.80

range from those requiring little input (low-level programmes) to those which are intensively managed

(high-level programmes). The programmes implemented appear to differ between zoo associations; however, there are many similarities in the way they function (see Table C.2). Essentially, Taxon Advisory Groups (TAGs) coordinate breeding efforts for a particular group of animals; the number of species represented can vary from as few as two in an elephant TAG to the many species included in invertebrate and reptile TAGs. Discussions between TAG members prioritize which zoo-held species need to be managed and what level of management they will receive. A variety of factors will influence this decision, including: (i) *in situ* and *ex situ* population numbers; (ii) the role of the species in conservation, education, research or recreation; (iii) the level of expertise required to maintain the species; and (iv) how many people with appropriate expertise are available to maintain the animals, etc.

The simplest level of management programme involves keeping a tally of the number of animals in captivity each year. From this information the TAG can assess changes in the population over time and consider whether or not more intensive management is needed. High-level captive breeding programmes revolve around the information collected and analysed in the studbook, to assess the success and future plans for the programme. Recommendations are made to zoos holding the species to ensure that future breeding and moves between zoos results in a genetically diverse population with limited inbreeding. These programmes usually have long-term management plans and produce husbandry guidelines to facilitate these goals. Many of these high-level programmes are integrated with *in situ* conservation or reintroduction efforts.

Captive breeding programmes face many challenges. Frustratingly, animals recommended for breeding might not breed successfully yet offspring are produced from nonrecommended pairings. This may be due to failed contraception, moves not occurring quickly enough, mismatched animals or simply bad luck. Analyses of genetic data may suggest unrealistic manipulations to maintain genetic diversity and limit inbreeding. For example, the number of individuals necessary to maintain 90% genetic diversity over 100 years may exceed that available within zoos. Logistical problems may in themselves make moves between zoos and breeding of 'ideal' animals difficult.

Many zoos worldwide, however, implement a variety of husbandry techniques, from single-sex housing and cessation of breeding and **artificial insemination** to environmental and social manipulations undertaken to achieve the recommendations made by studbook keepers. It is through these cooperative captive breeding programmes that many species have defeated the threat of extinction. Captive breeding successes include the Arabian oryx, golden lion tamarin, Mauritius kestrel and Round Island boa.

Captivity

Captive animal environments are diverse and include private homes, farms, ranches, **animal shelters**, laboratories, **zoos**, **circuses**, sanctuaries and others. While there is discussion on the ethics of keeping animals in captivity, a great deal has been gained and learned from captive animals. Some questions in

which scientists are interested can best be answered by studying captive animals. For example, natural communication patterns among chimpanzees might best be answered by studying wild chimpanzees, but questions about whether chimpanzees are capable of learning symbolic communication are best answered in a captive setting.

One method for operationally defining animal welfare is to compare the behaviour of captive animals with that of their wild counterparts (see: **Measuring welfare**). Greater similarity between behaviour in the two settings indicates improved welfare of the captive animals. While this approach has limitations, it has proved useful. Some have proposed that captive environments could be evaluated by how well the animals therein would be expected to cope, were they to be released into the wild.

Recent trends in captive animal care place greater emphasis on the naturalization of captive environments. Enclosures are larger and more complex, with more natural materials, social groupings are more species-appropriate and enrichment procedures are offering challenges. In these ways, captive environments are becoming more 'wild'. On the other hand, habitat destruction and the rapid growth of the human population bring humans and wild animals into closer proximity. **Wildlife management** programmes removing or relocating animals, ecotourism programmes bringing humans directly to animals and **reintroductions** of captive animals to the wild are all examples of the increasing role of humans in the lives of wild animals. The combination of better modelling of the wild in captivity, and an increased direct influence of humans on animals in natural settings, is blurring some distinctions between captivity and the wild.

Cardiac output

The term cardiac output (CO) refers to the amount of blood being pumped by the heart in a given period of time, usually per minute, and can be roughly calculated by using the following equation: $CO \text{ (ml/min)} = \text{heart rate (beats/min)} \times \text{stroke volume (ml/beat)}$.

(RM-F)

P.81

Carnivore

Carnivores eat the flesh of other animals. As adults, they typically have dentition that assists in the prehension of prey and allows cutting and chopping of muscular tissues (meat) and crunching of bones. Carnivores may be solitary or social species, with some being able to switch between the two as food availability and size dictate.

(PCM)

Cartesianism

René Descartes' view of the world, as being divided into two major substances - the mental and the material - influenced a school of thought known as Cartesianism. Cartesians adopted this duality of mind and body. Taking this reasoning to its practical conclusion, Cartesians of the day believed that they were doing nothing wrong by nailing living dogs (which did not possess the relevant kind of consciousness) to boards and cutting them open without anaesthesia. Whatever 'painful' yelps that emanated from these research animals were dismissed as inconsequential.

Today, contemporary British philosopher Peter Carruthers, who speaks from a contractarian view, argues for a position consistent with the Cartesian line that animals do not possess conscious experiences in the morally relevant sense. Like Cartesians, Carruthers emphasizes the dissimilarities that exist between human beings and animals. Although accepting that animals have sensations and leaving it open that they have beliefs and desires (not founded upon propositional language), Carruthers contends that what matters from a moral point of view is the capacity to form beliefs about one's beliefs. Since animals' mental states are 'not able to be consciously thought about [by subsequent thought] ... human beings are unique among members of the animal kingdom in possessing conscious mental states' (Carruthers, 1992).

Carruthers' argument, which rests on the premise that animals are unable to think about their thoughts, is a result of his commitment to a Higher Order Thoughts Theory of Consciousness. In this view, a mental state or experience is conscious just in case it is available to a thought that in turn is available to be thought about later. That is, to possess a conscious mental state requires something like 'access' consciousness and for one's mental states to be related to other mental states in the way described above. Carruthers contends that the inability of animals to reflexively access their thoughts rules out their capacities for 'representing to themselves different possible futures'. Furthermore, from a moral point of view, animals are not hardwired to reciprocate, because not only are they unable to adopt or agree upon social conventions and rules for moral conduct, but they also lack conscious experiences for guidance of behaviour. Carruthers holds that all animal consciousness can be likened to the unconscious event of 'absent-minded driving', where one is on autopilot.

A few concerns can be raised against Cartesians. First, it is unclear why exactly being able to retrieve one's thoughts or having higher-order beliefs is a necessary condition for being conscious in the morally relevant sense. Empirical observation contradicts the view that something like higher-order thoughts (i.e. rational abstraction or reflective consciousness) precludes animals from having phenomenal experiences like pleasure and **pain**. Furthermore, pain appears to be directly experienced and one's memory of pain does not appear to have the same qualitative feel as experiencing a painful event at the moment of occurrence.

Cognitive ethologists and animal welfare scientists like Donald Griffin, Marc Bekoff and Marian S. Dawkins, and many others, provide interesting insights into the cognitive powers and affective states of animals. Their research threatens the Cartesian contention that animals have no minds and are merely on autopilot. Furthermore, their research raises interesting philosophical questions about whether propositional language is necessary for **communication**. Perhaps animals have their own languages and communicate their thoughts in ways we cannot fathom. This latter insight raises questions about the propriety of judging the capacities of animals from a human-centric view. From an empirical point of view, these researchers also offer evidence that (reasonably) debunks some of the so-called 'uniquely

human' abilities, like access to previous experiences, use of previous experiences to guide behaviour or general flexibility while interacting with one's world.

Caslicks

The Caslicks procedure is a surgery performed on the vulvar labia of the mare. This surgery is typically indicated in broodmares with a perineal conformation that might predispose the mare to uterine infections. Anatomical features that may be indications for the Caslicks procedure include poor contact or seal between the labia and a recessed anus, with cranial tipping of the vulva. These may be associated with poor body condition, age or parity. Mares with such conformational defects are often called 'windsuckers' because of the airflow permitted through the poor seal of the vulvar lips. The Caslicks procedure is often used on young female racehorses because of presumptive poor performance secondary to 'windsucking' and vaginitis.

This procedure is normally performed with the mare standing, and local anaesthetic infiltrated into the labia. A narrow strip of tissue crossing the mucocutaneous junction of the labia, from the dorsal commissure and extending to the approximate level of the pelvic floor, is excised and reapposed with sutures (Beard, 1991). With the surgical wound healed the mare has only a short ventral opening for the evacuation of urine (see Figs C.1. and C.2). The vulvar lips are surgically reopened prior to parturition; this is normally performed with only manual restraint of the mare, or with restraint and local anaesthetic. An episiotomy is less frequently performed along with the Caslicks: the vestibular mucosa cranial to the labia is dissected and the edges apposed to create a narrower vestibular lumen.

Another surgical procedure performed on the external genitalia of the mare is the clitoral sinusectomy or, more rarely, a clitoridectomy, as an aid in preventing the spread of transmissible venereal diseases. The greatest concern is *Taylorella equigenitalis*, the organism causing contagious equine metritis, which is commonly harboured in the clitoral sinuses.

P.82

Fig. C.1. A strip of tissue at the mucocutaneous junction of the vulvar labia has been removed.

Cultural practices in certain human populations also incorporate surgical altering of the female external genitalia. Commonly called female circumcision or female genital mutilation, these surgeries may include clitoridectomy and excision of the labia minora and labia majora, with reapposition of the tissue edges similar to that performed in the Caslicks procedure. While numerous medical complications have been associated with this practice in humans, no systematic review of medical or behavioural consequences of the Caslicks, episioplasty, clitoral sinusectomy or clitoridectomy in the mare has been reported.

Castration

The term castration is sometimes used to refer to the neutering of either sex; however, this article will focus on its more common usage, i.e. the neutering of males. Not all male animals are required for breeding purposes, and they may have characteristics that would be undesirable in their offspring. Additionally, adult male animals can be difficult to handle and control because they fight with other adult males, are difficult to restrict or confine if there are oestrous females in the vicinity and may be aggressive towards handlers. Consequently, most young males are castrated, which involves removal or destruction of their testicles, resulting in dramatically reduced levels of circulating testosterone and the physical characteristics and behaviours that are largely controlled by this hormone. Thus, castrated males do not develop physical male secondary sexual characteristics, show fewer aggressive (**see: Aggression**) and **agonistic behaviours**, fewer **sexual behaviours** and tend to be easier to control and handle.

Castrated male livestock tend to have reduced liveweight gains, poorer feed conversion efficiencies and higher proportions of body fat than entire males at a given liveweight and, in some countries, castrated cattle (steers) are implanted with hormonal growth promotants to make liveweight gains and carcass composition more similar to entire males.

A number of devices and techniques are used to perform castration in livestock: (i) the bloodless castration clamp (e.g. burdizzo), which is applied for 5-10 s, two or more times to the scrotal neck in order to crush the spermatic cord without breaking the skin; (ii) the application of tightly fitting elastrator rubber rings or bands, which cut the blood supply to the testicles so that the scrotal and testicular tissues shrivel and eventually drop off; and (iii) surgical removal by cutting open the scrotal sac, removing the testes, cutting the *vas deferens* and

P.83

breaking/cutting the blood vessels. These techniques are used with and without **anaesthesia/analgesia** and control for haemorrhaging by, for example, applying an emasculator or ligature, and cautery. Deaths from post-castration haemorrhage have been reported.

For livestock, the age at which castration can be conducted, whether it can be performed by the farmer or a veterinarian and the requirement for local anaesthetics are dependent upon the species and country in which it is performed. In general, rubber rings are used for young animals (a few days to a few weeks of age), and the clamp and surgery are used in animals of several weeks to several months of age. In recent years a variation of the rubber ring technique (the application to the neck of the scrotum of thick latex bands, which are then ratcheted to a high degree of tension using a special hand-held instrument) has been promoted for bulls of 12 months of age and older.

Extensive research has been conducted on castration, particularly in lambs and calves, although most of the lamb studies have involved a combination of castration and tail docking (**see: Docking - tail**). Castration studies have compared different techniques and the effects of using anaesthetics and analgesics, and the majority have used behavioural and plasma cortisol changes as indicators of stress and pain. Most have concentrated on the few hours post-castration and there can be little doubt that castration causes considerable acute (up to 12 h post-castration in calves) pain regardless of the technique if anaesthetics and analgesics are not used. There is some evidence that chronic pain can last for at least 42 days in calves castrated at ages ranging from 1 to 36 weeks. In calves, the use of a local

anaesthetic (e.g. lidocaine hydrochloride/lignocaine) reduces plasma cortisol for up to about 1.5 h post-castration, whereas a systemic analgesic, such as ketoprofen, has been reported to reduce plasma cortisol to pre-castration levels. Reductions in feed intakes and average daily gain have also been reported in castrated calves for periods of up to 28 days post-castration. In addition, if techniques are used that result in open wounds, there can be complications at the site of castration, such as infections, abscesses and 'fly strike' (fly larvae burrowing into and feeding on the tissue).

In cattle, castration at a young age (less than 3 months) is desirable, as there is some evidence that it results in less stress and pain. In lambs there appears to be no evidence that younger animals suffer less pain than older ones. Indeed, in one study, younger lambs appeared to experience more pain from surgical castration than did the older animals.

A number of studies have shown that surgical castration in calves and lambs results in greater stress in the hours following castration, as indicated by increases in plasma cortisol levels, compared with other methods. Although there are some contradictory results, it appears that the clamp has the least effect on growth rates, fewest complications at the castration site and lowest responses in terms of plasma cortisol and behavioural changes. However, it is not always effective, and a failure rate of 10% has been reported. The use of rubber rings for calf castration is reported to cause pain in the first 3 h after administration, chronic pain for up to 7 weeks post-application and abscesses. Castration by latex banding has been shown to cause necrotic wounds in 14-month old bulls, which persisted after the scrotum was lost (at about 56 days post-banding) and took several weeks to heal. Banded animals also had lower growth rates than surgically castrated animals for a 56-day period post-castration.

Severe lesions of the type found to result from latex banding in cattle have not been reported following the use of rubber rings in 1-week-old lambs, but have been seen in 3-week-old animals. Some work indicates that a combination of the application of a standard rubber ring followed immediately by application of the clamp distal to it causes less acute pain than rubber rings alone. However, the position and duration of application of the clamp appear to be critical in effecting a reduction in plasma cortisol levels. It has been suggested that the clamp disables innervation of the skin and tissue distal to the ring, and that the ring prevents inflammation in the dying tissues. Hence the first application destroys the blood supply and innervation and subsequent applications should, therefore, be made below the first. There is, also, evidence that application of the clamp promotes more rapid healing.

Less invasive methods of castration have been tried, for example injection of lactic or α -hydroxy-propionic acid into the testes, which causes sclerosis and atrophy. Several studies (on cattle ranging from about 3 to 9 months of age) have indicated that the method is not always effective in causing testicular atrophy and sterility. Furthermore, a proportion of animals (18-50%) can show development of secondary sexual characteristics. This method is reported to take about three times as long as surgical castration to conduct. There are conflicting reports as to whether chemical or surgical castration induces more acute stress and pain; one study reported higher plasma cortisol levels in surgically compared with chemically (α -hydroxy-propionic acid) castrated animals, while another stated that behavioural changes indicated greater pain in chemically (lactic acid) castrated than surgically castrated calves. The results from the latter study indicated that lactic acid caused scrotal necrosis in some animals, and wound healing times were about twice that of surgically castrated calves.

More recently, alternatives to castration have been explored, such as immunization against **gonadotropin-releasing hormone** (GnRH) and GnRH agonists. Immunization against GnRH is reported to reduce or eliminate the reduced growth rates and feed efficiency associated with castration, provide carcass quality comparable to steers and reduce aggressive and male-male sexual behaviours.

Cat

A carnivorous mammal of the taxonomic family Felidae, which is characterized by its sharp teeth and claws and also includes the big cats (e.g. lions) that can roar and the smaller wildcats (e.g. ocelots) that cannot. Most cats are relatively solitary, coming together only for breeding, the exception being lions, which live and hunt in a socially cooperative way. Domestic cats will live in loose social groups, which in the feral situation typically consists of female siblings or relatives, which may cooperatively rear young and show some affiliative behaviour.

P.84

The domestic cat - which is variously known as *Felis silvestris domesticus*, *F. domesticus* or *F. catus*, is a domesticated variant of the small wild cat (*F. silvestris*) - is believed to have diverged from its nearest wild relative (*F.s. lybica*) over 100,000 YBP, although the earliest evidence of close human association dates to only 9500 YBP, to a shared cat-human grave in Cyprus. This date is quite closely associated with the development of agriculture by man, and the domestic cat almost certainly arose as a result of a commensalism with humans who stored grain which thus provided concentrations of rodent prey for the cat. Recent work suggests that the domestic cat appears to show some behavioural changes typical of domestic **companion animals**, such as increased attachment and attention to human cues, though these features are not as strong as they are in the domestic dog, and no studies have compared domestic cats to their wild relatives. There are five distinct subspecies of the wild progenitor, which appear to have started to diverge about 230,000 YBP: *F.s. lybica* (Near Eastern wild cat), *F.s. ornata* (Central Asian wild cat), *F.s. cafra* (Southern African wild cat), *F.s. silvestris* (European wild cat) and *F.s. bieti* (Chinese wild cat).

Domestic cats are now one of the most popular companion animal mammals and are found in homes throughout the world, with over 76 million estimated to be living in the USA and 47 million in Europe (Pet Food Manufacturers Association). In industrialized countries they are increasingly kept indoors, sometimes because of local restrictions aimed at protecting indigenous wildlife (e.g. parts of Australia).

Domestic cats are well known for their predatory behaviour and, while they can kill large numbers of small mammals and birds, their impact on the ecology of areas where they are indigenous or their potential prey covers large geographical regions is more debatable. However, they undoubtedly have had an effect on smaller island wildlife populations where they are not indigenous (**see: Exotic species invasion**) and where local species have no similar natural predator, e.g. the almost flightless ka'kapo (New Zealand owl parrot) and, most famously, the Stephen's Island wren, whose entire population was wiped out as a result of the introduction of a single cat by the island's lighthouse keeper.

Although domestic cats are carnivores and are unable to synthesize taurine, dictating the need for a meat diet or one supplemented with this amino acid, they also eat invertebrates and some plant matter as a matter of routine. The maintenance of both large and small cats in captivity has given rise to welfare concerns. Large and small wild cats, despite their natural tendency to spend up to three-quarters of the day sleeping or resting (being **crepuscular** in their activity patterns), appear to be particularly prone to showing locomotor **stereotypies** when kept in restricted, barren or frustrating environments. This is not a common problem of domestic cats, although they will show stereotypic oral behaviours (**pica**: including fabric eating and self-grooming behaviours resulting in substantial hair loss; see Fig. C.3).

However, confinement within the home may give rise to other problems. It has been suggested that cats without access to the outside are at increased risk of a number of physical diseases, including interstitial cystitis (bladder inflammation), resorptive lesions of the teeth, obesity and hyperthyroidism. The relationship between these problems and **stress** is variable, with a physiological mechanism explicable in

the case of cystitis; however, recent work suggests that the increased risk of hyperthyroidism may not relate to stress but rather to exposure to fire retardants used in some home furnishings.

None the less, keeping domestic cats indoors undoubtedly reduces the impact of their **predation** and the risk of injury or death in road traffic accidents, which are a major cause of **mortality** in this species. Homes can be enriched by exploiting the available three-dimensional space to make it more usable, since cats often prefer high-perch resting places (see Fig. C.4). Such environmental enrichment, together with appropriate provision and distribution of other key resources (feeding and drinking areas and latrines, together with safe passages to each) may also allow multiple cats to live together in a single home relatively peacefully, even if they do not form a social bond. The **personality** of domestic cats is an area that has attracted research and it appears that distinct types relating to their sociableness are consistently revealed. This has implications for the selection of cats to live together within multi-cat households, which are becoming more popular.

Dependence on solitary predatory behaviour, together with origins in an arid environment, are major influences on the nature of cats. Cats are generally quite heat tolerant, but may be subject to chilling when wet. They have largely binocular stereoscopic vision which allows them to judge distances well, and their hearing extends up to the ultrasonic frequency range (64 kHz), which helps with both the detection of auditory signals emitted by rodents and the localization of sound. Olfactory communication is perhaps the predominant medium between cats, with facial rubbing and **urine** spraying resulting in the deposition of chemical signals. Contrary to popular reports, the function of non-sexual urine spraying remains unclear, with many hypotheses being inconsistent either logically (e.g. a signal that helps indicate recent hunting activity success is unlikely to be a stable strategy) or from the available data (e.g. their use as territorial marks). Cats may also use faeces in communication (middening) as well as scratching, both of which convey information visually and chemically. Taste appears less well developed, with cats lacking the ability to detect sweetness.

Cats are seasonally polyoestrous in their reproductive behaviour, being quite vocal and often urine spraying when in season. These characteristics, together with induced ovulation and superfecundity (use of several males to father a litter), help to maximize local genetic input during breeding. Typical litter sizes are between three and five kittens and may be reared collectively by feral cats in female colonies, usually of related individuals. The feeding of feral cats can result in very high local population densities, with an increased risk of disease and potentially public health problems as a result. The tendency to keep cats indoors and a failure to appreciate their nature are major reasons for the surrender of cats to **animal shelters** (see also: **Abandoned animals**), other common reasons relating to changes in living condition and allergic responses among family members, although some breeds (e.g. Devon rex) appear to be generally less allergenic.

Fig. C.3. Domestic cat showing bilateral hair loss, which can arise as a result of stress-induced stereotypic hair pulling (image courtesy of S. Pipan).

Cat breeding has resulted in relatively little breed diversification on the original body form, compared with dogs, although specific mutations are now being preserved by some to create new breeding lines with distinct musculoskeletal or dermatological features (e.g. taillessness, dwarfism, hairlessness, folded ears, etc.). Some national associations refuse to recognize such animals as breeds, due to their associated health problems.

Catecholamine

Catecholamines fall within the amine class of neurotransmitters and hormones and include: **epinephrine** (adrenaline), **norepinephrine** (noradrenaline) and **dopamine**. These catecholamines are important in determining how the body responds to **stress**. All three are synthesized from tyrosine in sympathetic nerve cells, and derived sequentially from one another through the conversion of dopamine to norepinephrine, which in turn can be converted to epinephrine.

Cathemeral

Cathemeral refers to a pattern of activity that is neither nocturnal nor diurnal, but more sporadic through both day and night. This activity pattern was first documented in lemurs by Tattersall (1979).

Cattle

Types of cattle

Cattle were first domesticated about 9000 YBP and, since that time, they have become the major meat and milk producer in the world. They evolved from the aurochs, or *Bos primigenius* cattle, in two distinct subtypes, *Bos taurus* (European cattle)

P.86

and *Bos indicus* (zebu cattle). Originally, it is believed, cattle were enticed into a symbiotic relationship with humans by offering salt and other food necessities. The last wild cattle from the *Bos primigenius* subtype were exterminated in Czechoslovakia in the 17th century. The two distinct subtypes, European cattle and zebu cattle, have been established as suitable domestic breeds for cool temperate and hot tropical conditions, respectively. The European-type cattle have been bred for high productivity because of the more suitable climate. Selected lines have been developed for milk and meat production, with the most popular of these for milk production being the Holstein-Friesian, which can have **lactation** yields of over 10,000 l, or several times a calf's requirements, and cows will lactate for approximately three-quarters of their life in the dairy herd. For meat production the **double-muscle** breeds, such as the Belgian blue, are increasingly popular, with growth rates exceeding 1.5 kg/day and a high muscling characteristic in the body, which can lead to dystocia problems in purebred calvings.

Major welfare concerns in cattle

The selection of cattle exclusively for the output traits in the milk and meat production breeds has given rise to many welfare problems, especially when they are kept in intensive conditions, for economic reasons (**see: Intensification of animal production**). The Holstein-Friesian cow tends increasingly to be kept year round in a concrete-floored barn system, supplied with feeds that have been conserved so that they can be stored and fed mechanically. The high productivity of intensively bred milk and meat production animals requires the feeding of energy- and protein-rich foods, so that the natural ability of cattle, as ruminant animals, to digest coarse plant fibres with the aid of the microorganisms in their rumen, is circumvented. The feeding of wet, acid silage (grass preserved in the acid byproducts of bacterial fermentation) leads to the production of low-dry matter faeces. Unless this is cleaned regularly from the floor, the enforced standing of dairy cows in a wet slurry of faeces and urine, on concrete, and with only narrow, concrete beds to lie on, gives rise to some serious lameness problems that are undoubtedly very painful for cows. The principal of these is **laminitis**, exacerbated by the feeding of energy-rich diets. These and other lameness problems caused by the environment that the cows are kept in can give rise to a prevalence of lameness in dairy herds of over 20%.

The prevalence of faeces in the cows' environment encourages farmers in intensive dairying regions to dock the tails of their cows, which prevents them being used to remove flies from the cows' body or as a signalling agent (see: **Docking - tail**).

The other major problem for the health of the dairy cow is **mastitis**, or intramammary infection, which is increasingly due to environmental pathogens invading the mammary glands via the teat canal, when the cows are lying on soiled bedding. Although many improvements have been made in hygienic management of dairy cows in the parlour and in the early detection and treatment of mastitis, the prevalence of the disease has not declined, largely due to the emergence of novel pathogens that colonize the mammary gland in her environment, rather than the milking parlour, which is now routinely disinfected between milkings.

Another concern for the high-yielding dairy cow is the limited amount of time that she has to eat sufficient food to supply the nutrients for production of perhaps 50-70 l/day of milk. It has been postulated that the high-yielding dairy cow in early lactation is permanently hungry, even though she is likely to have conserved feeds or pasture available for most of the day. Time available for lying down will be limited and so she may be permanently tired, as well as hungry. The average longevity of high-yielding dairy cows is usually no more than about three lactations so, given a 2-year rearing period, they live for approximately 5 years in total compared with their potential lifespan of about 25 years.

Apart from lameness and mastitis, one major reason for premature **culling** is reproductive failure, since cows that mobilize a lot of their own body's adipose reserves to support the high milk yields do not readily conceive. Conception rates in high-yielding dairy cows have declined significantly since the late 1980s, from about 60% down to about 40% in some herds. Reduced manpower to detect oestrus in cows is also partially responsible for poor reproduction rates. As well as the use of genetics to increase the potential milk yields in the dairy cow, an artificial **growth hormone**, bovine somatotropin, has been developed that will increase milk yields and have similar adverse effects on the cow's welfare to increasing productivity through genetic selection. The use of this artificial growth hormone is common in some intensive dairying regions, such as in the USA, but is prohibited in the European Union and Australia.

The development of separate lines in *Bos taurus* cattle for the production of meat and milk has led to some ethical and welfare problems for the offspring of dairy cows. Male calves are often of little value and may be killed soon after birth. Alternatively, they may be transported to a market and transferred to a cattle-rearing farm, but the quality of meat from calves that originated in the dairy herd is much below that of beef calves. Considerable attention is usually given to the rearing of the female replacements for the dairy herd, and their subsequent development into dairy heifers. However, the transition from a rearing unit to the dairy herd, including passing through a milking parlour two or three times a day, is inevitably a difficult one. The change in diets alone can cause significant lameness problems, but the mixing of young heifers with adult dairy cows can lead to a period of aggression and discomfort for both cows and heifers.

Intensively reared cattle suffer from inadequate space and metabolic diseases associated with the feeding of highly concentrated feeds, including acidosis and laminitis. Entire male cattle grow faster than castrated cattle, but they are more likely to have behaviour problems, such as riding each other and fighting. Excessive riding can cause broken penises and suffering on the part of the ridden cattle. Most cattle, however, reared on extensive pasture or rangelands, particularly in Australia and the USA, will utilize their ability to digest coarse fibre on grassland, rangeland or other land that cannot grow crops for human food. These land areas are not only less productive, often because of poor soil types, but they are also subject to very variable rainfall, and hence the unreliable quality and quantity of pasture grown provides a more variable feed supply than that offered to intensively kept farm animals, such as pigs and poultry, for example.

The ability of cattle to deposit adipose tissue when there is plenty of grass available, and then to mobilize it to sustain productivity when there is little feed available, has made them an extremely successful animal to utilize the extensive rangelands of the world today. However, some cattle farmers may be tempted to keep too many cattle in times of drought, because the loss of a breeding herd has a major impact on the farm's economic potential for future years. In times of drought farmers should sell cattle, provide them with supplementary food or rent lands for grazing. Nevertheless, inadequate supplies of food for cattle in times of drought do lead to significant cattle mortality.

In Australia, many cattle are reared in breeding herds on rangelands and they are then transported to **feedlots**, where they are kept at a high stocking density and fed conserved feeds, usually based on high-quality cereals. High temperatures will challenge such stock at high densities, and significant mortalities can result from a heatwave. The provision of shade is a simple but effective technique in ameliorating high temperatures (**see: Shade-seeking behaviour**).

Traditionally, the movements of cattle between farms or to markets or the abattoir was along droving routes, which provided an opportunity for animals to feed while they were moving. More recently, though, it has become normal for cattle to be transported in vehicles or by train. Many rangeland farms are a long distance from the destination of cattle, which then become tired, hungry and thirsty. Some cattle are transported overseas on ships, with journey times typically from 1 to 3 weeks. On the ships they are fed a pelleted ration and provided with water, but stocking densities are high and cattle may have difficulties adapting to conditions overseas (**see: Transport**).

Cattle are still used for draught, pulling ploughs, other machinery, carts or occasionally hauling timber. Because the work that the cattle have to do takes most of the day and they are often corralled into a small enclosure at night for safety, the biggest problem for these animals is inadequate food supply. As well as working for farmers they may also produce dung for fuel, which is a valuable commodity in subsistence economies. In India the heavy reliance on cattle for milk products, work and the production of dung has led them to be regarded as **sacred animals** by the Hindu population, so that they cannot be killed but are allowed to roam the streets. Because of restricted land availability many cattle have to scavenge on the streets and can eat plastic bags and other rubbish that is of no nutritive value. India has the largest cattle population in the world, and much remains to be done to improve the welfare of cattle in that country. In Muslim countries cattle are usually killed according to the principles of the Islamic faith, with a sharp knife cut to the neck to allow rapid exsanguination. No stunning is permitted, and hence the time to unconsciousness will be longer than in Western countries, and this has raised concern about their welfare (**see: Religious slaughter**).

There has been much criticism of the welfare of cattle in recent years, as well as their impact on the environment and on the health of the consumer. However, their ability to utilize poor-quality lands will ensure that they remain one of the foremost food producers in most countries of the world. They can be kept in both hot and cold climates and in diverse environments. Their endogenous heat production makes them particularly well suited to cold climates, but the heat stress resistance of *Bos indicus* cattle renders them particularly well placed to cope with tropical and subtropical conditions, as long as high productivity is not required. Being one of the most popular food production animals, there has been considerable research into the welfare of cattle, and major advantages to welfare could be gained from effective implementation of current knowledge.

Causal factor

How an animal behaves at any point in time depends upon what factors are motivating it at that time. The animal will be influenced by external factors, such as the environment or social situation, as well as by internal factors such as hunger or hormone levels. The **brain** monitors changes in all of these factors and interprets them, using the animals' previous experience of the situation, in order to make a decision as to what the animal will do. While many different factors may be influencing the animal, some of them will trigger particular behaviours, such as **stereotypies**, and these are referred to as causal factors.

In some cases the causal factor for a behaviour can be easy to distinguish; for example, hunger triggers foraging behaviour. However, in other cases it can be much more complex, such as with **feather pecking** in chickens, where one individual pecks at the plumage of another. Some studies suggest a lack of **dustbathing** substrate is the causal factor; however, other studies suggest that the behaviour may be derived from foraging motivation. There has been no conclusive evidence that there is one specific causal factor, and it may be that a number of causal factors play a part in the expression of the behaviour.

When keeping animals intensively, **welfare** issues can result from internal causal factors motivating behaviours that cannot be performed in the environment in which the animals are being kept. A classic example of this is in pregnant sows; as they approach farrowing time changes in hormone levels cause them to become highly motivated to nest build. Since the causal factor is internal it occurs even when the environment is not suitable for nest building, e.g. when they are kept in a barren **farrowing crate**. The **frustration** that results from being unable to fulfil this behaviour can cause a prolonged birthing process and higher levels of stillbirth.

(PoS)

Central nervous system

The central nervous system (CNS) consists of the spinal cord and the **brain**. The spinal cord lies in the vertebral canal, whereas the brain is located in the cranial cavity. The functions of the CNS are to receive, identify, integrate and interpret incoming sensory stimuli from the body's internal and external environments, then produce electrochemical impulses that are

P.88

transmitted to the body's effector organs (muscles and glands) via the **peripheral nervous system**, including the **autonomic nervous system**, to initiate appropriate responses to the stimuli (adaptation). The responses aim to satisfy an organism's physiological requirements, such as survival, experience of positive emotions, avoidance of negative emotions and learning to improve performance. Disorders of the CNS may result in a permanent impairment of sensory, memory and motor functions, which affect animal well-being.

General structures of the central nervous system

Both the spinal cord and the brain are wrapped in three layers of connective tissues (meninges). They are, from inner to outer, the *pia mater*, the arachnoid, and the *dura mater*. The subarachnoid space lies between the *pia mater* and the arachnoid, filled with cerebrospinal fluid (CSF).

The cerebrospinal fluid is a clear, watery fluid that is produced by vascular plexuses (choroid plexus) in the ventricular system, and exits the CNS through the arachnoid villi. The CSF circulates within the ventricular system and the subarachnoid space. The ventricular system consists of a thin central canal of the spinal cord, the fourth ventricle of the medulla and pons, the third ventricle of the diencephalon and two lateral ventricles (representing the first and second ventricles) of the cerebrum. The essential function of the CSF is to prevent the spinal cord and the brain from both physical and physiological damage. The CSF provides physical supports for the brain and the spinal cord and maintains a relatively constant nutritional environment, including glucose, proteins and salts, for the neuron(s). Analysis of the CSF, such as for pressure and contents, is important in the diagnosis of many conditions affecting or damaging the brain and the spinal cord, such as infection, haemorrhage and mental retardation.

The brain receives arterial blood from a cerebral arterial circle fed by the internal carotid and the vertebral arteries. The venous blood is collected in cerebral veins (deep and superficial), passes to the sinuses and exits the brain for the systemic circulation through the internal jugular vein. The spinal cord receives arterial blood at different levels via the anterior and the posterior spinal arteries. The venous blood is collected in a venous plexus at the surface of the spinal cord, then passes to the epidural plexus at the surface of the dura and, finally, to the veins outside the vertebral canal. Damage to blood supply, such as from infarction, haemorrhage or atherosclerosis, may permanently impair brain and spinal functions.

There are three barriers within the central nervous system: (i) between blood and CSF - the blood-brain barrier (BBB); (ii) the CSF-brain barrier (CBB); and (iii) the blood-CSF barrier (BCF), intercalated between the blood, CSF and brain to protect the neurons from damage and to allow cross-exchanges of certain substances that are required by the central neurons for survival and action.

Neural structures of the central nervous system

Based on the colouring of tissue sections, the CNS can be divided into the white matter and the grey matter. The white matter contains axons, some of which form the peripheral nerves (the spinal cord) and cranial nerves (the brain). The grey matter contains nerve cell bodies (somas) and dendrites.

The CNS - both the brain and the spinal cord - consists of nerve cells (neurons), a component of the CNS for conducting electric impulses, and neuroglial cells (glia), an element of the CNS for supporting neurons. Neuroglia include astrocytes (fibrous astrocytes located in the white matter and protoplasmic astrocytes located in the grey matter), oligodendrocytes and microglia. The functions of astrocytes include: (i) structural support for neurons by providing a net frame; (ii) functional support for neurons by isolating and grouping of nerve fibres and synaptic terminals; (iii) metabolic support for neurons via regulating ions, transmitters and metabolites; and (iv) pathological support for neurons by repairing and isolating damaged nerve tissue. Oligodendrocytes form a myelin sheet around the long axons (nerve fibres), which protects and modifies the axons needed to send signals over long distances. Microglia are small phagocytes scattered throughout the CNS. Following injury or degeneration of the nerve system, these proliferate and transform into larger macrophages, which defend against inflammation and infection by phagocytizing and removing the debris.

The brain and the spinal cord consist of billions of interconnecting neurons (nerve cells). Bundles of their axons form nerve tracts or pathways within the CNS. Based on their functions, in general, there are three types of neurons: (i) the afferent neurons (sensory neurons), inputting information that they receive from the internal and external environments to the CNS; (ii) the efferent neurons (motor neurons), bringing instructions that fan out from the CNS to the body's effector organs (muscle and glands); and (iii)

interneurons, receiving information from sensory neurons, processing that information, then sending the signals to the motor neurons by forming a complex, interconnecting electrical circuitry.

Neurons with the same or similar function integrate into a system (pathway), and there are four neuronal systems: (i) the sensory system, which acquires information about the external and internal environments; (ii) the integrative system, which processes the incoming information, evaluates this information within the context of past experience and makes decisions for action or inaction depending on the circumstances; (iii) the motor system, which converts decisions into commands for action (or inaction) by effector organs (muscles and glands); and (iv) the coordinating system, which organizes the patterns of commands to the effector organs to ensure operation in a smooth and efficient way. There are interactions among the different neuronal pathways within the CNS in response to stimuli.

Specific structures of the central nervous system

The spinal cord extends from the lower end of the brainstem down the vertebral canal. It consists of an H-shaped centre of grey matter and an outer zone of white matter. The grey matter contains neurons and their dendrites. Based on morphological and functional characteristics there are three major types of neuron: (i) afferent neurons (sensory neurons) located in the dorsal horn, the dorsal arm of the H, which receive input from skin and send their axons to the higher levels of the CNS; (ii) efferent neurons (motor neurons) located in the ventral horn, the ventral arm of the H, which send their axons out of the CNS to the skeletal muscles; and

P.89

(iii) interneurons located in both dorsal and ventral horns, which send their axons to other parts (segments) of the spinal cord. There is another group of neurons located in the intermediolateral cell column, belonging to the autonomic nervous system. This group of neurons send their axons out of the spinal cord to smooth muscles and glands through the ventral roots. The neurons located in the thoracic and upper lumbar segments of the spinal cord and in the sacral segment belong to the sympathetic and parasympathetic parts of the autonomic nervous system, respectively.

The white matter contains axons. Based on their functions, the axons are divided into funiculi or columns. There are three major types of axons conveying signals: (i) from the cord to higher levels of the CNS; (ii) from higher levels to the spinal cord; and (iii) between the segments of the spinal cord. Axons mediating communication between the CNS and other parts of the body make up the peripheral nerves (spinal nerves), which split into two parts, the dorsal root (sensory axons) and the ventral root (motor axons). These roots carry information to and from the spinal cord, respectively.

The spinal cord connects the peripheral nervous system to the brain and is involved in regulating sensory, motor and autonomic functions. Information from sensory receptors (nerve impulses) reaching the spinal cord through the dorsal roots is transmitted up into the brain. Signals arising in the motor areas of the brain travel back down the spinal cord and leave through the motor neurons via the ventral roots. Acting as a lower coordinating centre, the spinal cord is also responsible for some simple reflexes like the withdrawal reflex.

The brain is the major organ of the CNS. It controls vital functions, such as heartbeat, respiration, blood pressure and body temperature, and both sensory and motor functions. The brain also controls reactive functions, such as receiving and interpreting sensations from the nerves in response to stimuli, then initiating and coordinating those activities such as arousal, emotion and learning.

The brain consists of several specific structures that control physiological and psychological homeostasis.

The brainstem is the part of the brain that extends from the upper end of the spinal cord up the vertebral canal. It connects the cerebellum and cerebrum. It consists of the medulla (*medulla oblongata*), the pons and the mesencephalon (the midbrain), and the diencephalon.

The grey matter of the brainstem contains 10 of the 12 pairs of cranial nerves:

- oculomotor nerve (III);
- trochlear nerve (IV);
- trigeminal nerve (V);
- abducent nerve (VI);
- facial nerve (VII);
- auditory vestibular nerve (VIII);
- glossopharyngeal nerve (IX);
- vagus nerve (X);
- spinal accessory nerve (XI); and
- hypoglossal nerve (XII).

Many of the cranial nerves contain nerve fibres that conduct impulses out of the brainstem (efferent or motor fibres), while others bring impulses from sense organs (afferent or sensory fibres). Most cranial nerves are mixed, i.e. containing both motor and sensory fibres. There are four categories of cranial nerve fibres: (i) somatic efferent fibres, innervating skeletal muscles; (ii) visceral efferent fibres, supplying smooth muscle and glands; (iii) somatic afferent fibres, carrying sensory impulses from skin and mucous membranes; and (iv) visceral afferent fibres, transporting sensory impulses from the visceral organs. The white matter of the outer layer zone of the brainstem contains the major inflow and outflow nerve tracts from the brain and the spinal cord.

The brainstem plays an important regulatory role in basic functions, such as respiration, **blood pressure** and body temperature. The brainstem also acts as a highway for messages travelling between the other parts of the brain and the spinal cord. There are several major structures within the brainstem, including the reticular formation, the thalamus and the **hypothalamus**.

The reticular formation consists of groups of diffuse connections of scattered nerve cells throughout the core of the brainstem. It has functions in the central integration of coordination and in controlling the level of consciousness, which evoke preprogrammed or automatic reflex actions in response to stimulation. As an ascending activating system, it alerts the higher brain centres to the sensory stimuli, such as attention and consciousness, mental processes (mental state) and locomotory movement. The reticular formation also controls cardiovascular and respiratory functions, sleep, wakefulness and level of arousal.

The thalamus is located within the diencephalon, beneath the cortex and basal ganglia and above the hypothalamus. It consists of a massed group of neurons that are arranged into distinct clusters, named the dorsal thalamus, ventral thalamus, epithalamus and thalamic reticular nuclear group. It functions as a subcortical centre that influences visceral and somatic effectors, via the connections with the hypothalamus and the neostriatum. It also acts as a relay centre of sensory information to the cerebrum. All sensory input (except for olfaction) integrates in the thalamus, then forwards signals up to the somatosensory region of the cerebral cortex through the thalamocortical radiations. The signals from the somatosensory areas return to the thalamus on the way to the motor areas of the cerebral cortex.

The hypothalamus is located within the diencephalon. It consists of many smaller nuclei on each side of, or at, the midline. The hypothalamus is the principal integrating region for the entire autonomic nervous system. It produces hormones that affect other endogenous glands by which, it controls growth, sexual

behaviour, metabolism, fluid balance and many other physiological variables. The hypothalamus is the source of nine tropic hormones:

- antidiuretic hormone;
 - corticotropin-releasing hormone (CRH);
 - gonadotropin-releasing hormone (GnRH);
 - growth hormone-release inhibiting hormone (GH-RIH);
 - growth hormone-releasing hormone (GH-RH);
 - melanocyte-stimulating hormone-release inhibiting factor (MSH-RIF);
 - melanocyte-stimulating hormone-releasing factor (MSH-RF);
 - oxytocin;
-
- prolactin-release inhibiting factor (PIF);
 - prolactin-releasing factor (PRF); and
 - thyrotropin-releasing hormone (TRH).

P.90

The hypothalamus is the site that has close connections with the **pituitary gland** (the **hypothalamic-pituitary-adrenal (HPA) axis**) and serves to coordinate endocrine, autonomic and somatic motor functions to maintain body homeostasis in response to various stimuli, such as stress-induced changes of immunity, emotions and emotional reactions, mental functions and psychosomatic interrelations.

The cerebrum, the enlarged frontal structure of the brain, is divided into the cerebral hemispheres by the sagittal fissure. Each of the cerebral hemispheres contains a thick outer layer of grey matter (the cerebral cortex or *cortex cerebri*) and a central mass of white matter with some embedded nuclei, including the basal ganglia and the hippocampus. The surface of the cerebral cortex comprises gyri (folds) divided by sulci (fissures). Based on the borders formed by fissures and sulci and the main bones of the skull that overlie the cerebral hemisphere, the cortex is divided into four distinct lobes - the occipital lobe, parietal lobe, temporal lobe and frontal lobe, which can be further divided into approximately 50 cortical areas on a cytoarchitectonic basis.

The grey matter contains neurons that are arranged into six layers. The neurons receive impulses from and send impulses to lower parts of the CNS. The white matter contains nerve fibres that are organized into bundles (or nerve tracts). There are three main types of fibres: (i) association fibres, which link areas of the cortex within a single hemisphere; (ii) projection fibres, which link areas of the cortex to central brain structures and to the brainstem; and (iii) commissural fibres, including the *corpus callosum*, which link the two hemispheres.

The cerebrum functionally controls conscious thought, **decision making**, **perception**, **memory**, sensation, movement, speech and writing. The two hemispheres are lateralized with respect to function (hemispherical lateralization), i.e. in humans some higher activities such as speech and writing are controlled from one cerebral hemisphere, the dominant one (mostly the left hemisphere), whereas the non-dominant side (mostly the right hemisphere) is associated with visual/spatial orientation, artistic appreciation and creative thought, such as musical ability, facial recognition and the perception of social cues.

The cerebral cortex belongs to the grey matter and is rich in neurons. The neurons are arranged in six layers in a network manner, forming columnar sets among the vertically connected neurons. The cellular

columns are the basic communication and information-processing units. These units exchange impulses with lower centres of the CNS. Anatomically and functionally the cortex is divided into different regions, such as the motor cortex (voluntary movement), somatosensory cortex (sensibility), visual cortex (vision), auditory cortex (hearing), olfactory cortex (smelling) and the limbic system, including the hippocampal gyrus and its adjoining cortical regions (learning and memory). The functions of the cerebral cortex are storage, analysis and integration of sensory information received from the internal and external environments to produce higher cortical function, such as abstract thought, memory, learning and consciousness; and initiation of somatic and vegetative responses, such as volitional movement and cardiovascular and gastrointestinal function. Damage to the cerebral cortex may cause permanent impairment of sensory, memory and motor functions, depending on the area(s) affected.

The basal ganglia are masses of subcortical nuclei, including the caudate nucleus, the putamen, the *globus pallidus* and the lentiform nucleus. Among them, the caudate nucleus and putamen are named the neostriatum. They are connected to the brainstem and the cerebellum through various nerve bundles, and are functionally involved in modifying motor output from the cerebral cortex, i.e. signalling and coordinating movements of skeletal muscles. Damage to the basal ganglia or the striatum itself causes movement disorders, such as Huntington's disease.

The limbic system (Broca's limbic lobe or the Papez circuit) consists of several groups of neurons, including the cingulate gyrus, the hippocampal formation, the septal nuclei and the amygdala (some also include the mammillary nucleus and anterior thalamic nucleus). The limbic system receives inputs from various associated areas in the cerebral cortex and passes signals on to the *nucleus accumbens*. The functions of the limbic system are involved in long-term memory, learning and cognitive tasks (hippocampus), emotions, **fear** and **anxiety**, anger and **aggression** (amygdala).

The cerebellum ('little brain') is a massive, rounded structure located dorsal to the brainstem. It is linked to the brainstem by three thick nerve tracts (peduncles). The cerebellum consists of two hemispheres, which are further divided into lobes by the fissures and sulci. The cortex (the cerebellar cortex) of the hemisphere belongs with the grey matter and is rich in nerve cells, which are arranged in three main interconnected layers. In the white matter a central core consists of several nuclei, the central (deep) cerebellar nuclei.

The cerebellum functionally belongs to the motor system, which controls muscular coordination, balance and posture for the execution of movements. It receives information from organs such as muscle tendons and the balance organs in the inner ears, integrates the information, then sends the signals to the neurons of the nuclei and to the other regions of the CNS, resulting in smoothly coordinated movements and balance of the trunk and extremities. The cerebellum also regulates visceral function, such as heart rate and blood flow, during changes in posture.

(H-WC)

Cephalopods

Cephalopods embrace the octopuses, squids, cuttlefish and chambered nautilus. They are a class of mollusc. Cephalopod means 'head-foot', and the fact that cephalopods have their appendages, known as arms, branching from their heads distinguishes them from other molluscs. Cephalopods are an ancient group of animals that lived in the seas hundreds of millions of years ago. One extinct branch, the ammonites, is very well represented in fossil records. Ammonites had a coiled shell up to 1 m across - similar to present-day nautilus. Their relatives, the belemnites, had an internal shell and they probably gave rise to most of the present-day cephalopods. Two factors probably drove the ammonites and belemnites extinct: competition with fish and the extinction event at the end of the Cretaceous period 65 million YBP, popularly ascribed to the collision of a meteor. No fossils of ammonites

or belemnites have been found since that time, but a distant relative, the chambered nautilus, survives as a relict, a true living fossil.

Nautilus

Nautiluses have a coiled shell in which they live and to which they are attached. Like snails, they cannot be completely free of their shell. The shell is similar to a snail's shell, but serves a different purpose besides protection of the animal. A nautilus's shell is divided into chambers and it lives in the last outer chamber. The others are sealed, except for a thin thread of tissue that connects them and regulates the water level - and hence the air pressure - in each chamber. The animal thus regulates its buoyancy like a submarine. This is important, because nautiluses make daily vertical migrations on the reef face, upward at night and downward during the day, probably to avoid being seen by predators. Once they remove water from a chamber, they cannot readily replace it and, if they remove too much, they will float to the surface and be tossed around by wave action.

Today there are two genera of nautiluses extant, with only five or six species - one species has never been seen alive and is known just from shells washed ashore. This lack of diversity is one reason that nautiluses are considered a living fossil and that they may be dying out. They have a limited range in the tropical western Pacific, and several of the individual species are restricted to certain archipelagoes there. Also, thousands of these animals are being caught just for their shells, which are then sold in novelty shops to tourists and shell collectors. Because they are so limited in species and range, they are deserving of extra consideration, both in the wild and in captivity in aquariums or laboratories.

Other aspects of nautiluses' natural history, physiology and ecology also render them ripe for study. Their eggs have rarely been found in the wild and, although hundreds have been laid in captivity, few have hatched and they did not survive to maturity. Interestingly, hatchlings have several functional shell chambers capable of controlling buoyancy. Nautiluses appear to be the only cephalopod group that survives reproduction: all others are semelparous, i.e. they die after reproducing.

Preliminary indications indicate that nautiluses may live 10-15 years or more but, because they have not yet been reared to maturity, this is only a guess. If they live that long it would make them the longest-lived cephalopod, as others live only up to a few years. Although many aspects of nautiluses warrant further study, researchers must use prudence in working on them. They are difficult both to obtain live and maintain successfully. Their population status is unknown, mostly from lack of numbers and since they come from Third World countries. There is increasing evidence that they are being overfished and there is no regulation of their take.

Cuttlefish

Unlike nautiluses which are members of the subclass Nautiloidea, cuttlefishes and all the other cephalopods are coleoids. Cuttlefish have internal shells like their belemnite ancestors, although octopuses and squids have mostly lost theirs. The cuttlefish shell is thick and porous, providing structure and support to the body, as well as buoyancy. Cuttlebones sold in pet shops to supply calcium to psittacines are the shells of cuttlefish, obtained from animals used as human food or washed up on shores. Cuttlefish have eight arms and two long, prey-catching tentacles. They have two remarkable eyes replete with lens, cornea and retina. The eyes of cuttlefish and their kin have w-shaped pupils. The eyes are a good example of **convergent evolution**, as they are similar to vertebrate eyes. The eyes are used to find prey or mates, avoid predators and to help match their shallow water backgrounds in camouflage behaviour.

Most coleoids have the ability to change their colour using chromatophores in the skin, tiny cells that show their colour when stretched open by muscles under direct control of the brain. The chromatophores

can show black, brown, red or yellow, and other cells show white or reflect blue or green, which gives them quite a diverse palette to work with. They can open chromatophores of all one colour, say red, or show patches of colour to match a mottled background. In addition, they have fine control of the other muscles in the skin and are able to vary the texture of the skin as well as the colour, from smooth to bumpy or even spiked.

Cuttlefish can change the colour and texture of their skin in a fraction of a second. Chameleons and flounders, other animals considered masters of camouflage, may take hours to change their colour. Cuttlefish can even change their colour in waves running across their bodies. These are dark bars passing over a light background on the skin. These 'passing clouds' wash over the whole body in less than a second. They are probably used as signals to other cuttlefish, although they have not been studied in detail. Passing clouds have been described in octopuses as possibly being used to startle a motionless crab into movement so that it could be seen.

Cuttlefish are relatively easy to maintain in captivity. Institutions such as the National Resource Center for Cephalopods, in Galveston, Texas, have kept many successive generations of them and have supplied them to aquariums and research laboratories much as white rats are. Although about ten species have been kept in captivity, we know little about their behaviour in the wild and almost nothing about the other species. Cuttlefish mate head to head, when the male passes a sperm packet into the female. She stores the sperm until she is ready to lay eggs, usually in coral crevices or other hard substrate. The eggs are attached individually in a cluster adjacent to each other. The eggs are roundish, typically about 1 cm across, with a distinctive point at the end away from the attachment. Cuttlefish frequently incorporate ink into the eggs, making them dark or black. Hatchlings are about 1 cm long after several months of direct development inside the egg; there are no larval stages as in other molluscs. They begin feeding immediately on live food, crustaceans and fish. They look like miniature adults and can replicate most of the behaviours of the adults, like inking, changing colour and even burying in the sand to hide from predators. For burying they sit on the bottom, blow sand back and forth with their water jet funnel, allowing it to settle down upon themselves, then wiggle from side to side to 'settle' the sand.

Cuttlefish and most other coleoids have an ink gland that produces a dark brown or black ink, which they shoot out their funnels to confuse predators. They can incorporate thick mucus into the ink to create a thick ink blob, resembling the animal itself, or they can shoot it into a cloud like a

P.92

smokescreen to hide behind. Some cephalopods seem to be able to shape the ink blob just as smokers can blow a smoke ring. The ink may also have a noxious chemical in it, so it confuses both the sight and smell of a predator.

Only one cuttlefish species has been studied in detail, the common European cuttlefish *Sepia officinalis*, and its behaviours have not been studied well in the wild, although some of its habits were noted millennia ago by Aristotle. There are about 100 other species. Aquariums and research laboratories are just beginning to concentrate on the husbandry of some of these species.

Squid

Like cuttlefish, the 250 species of squid have eight arms and two long tentacles for catching prey, mostly fish. They have a fin on each side of the body used for slow swimming and manoeuvring, but their main propulsion is jetting by taking water into the body cavity and squeezing it forcefully out of the funnel in a water jet. The funnel is muscular and can be directed in all directions, so the squid can jet forward, backward and even sideways, although their fastest swimming direction is backward. When the fins are folded against the sides their torpedo-shaped bodies slide aqua-dynamically through the water, thus escaping from predators.

Squid also use schooling to avoid being eaten by predators, clustering together in groups of hundreds or thousands. Schools of shallow-water squid seem to disappear when a predator such as a bar jack or tarpon approaches - as a group, the squid turn a pale shade and jet away, frequently leaving ink blobs that resemble squid in their place to further confuse the predator. Since they school together, squid are the most social of the cephalopods but the behaviours have only been studied for a few species. Some squid get together in enormous groups to mate and lay eggs. Males grasp females and their arms turn bright red while they transfer a sperm packet to the female. Females lay white, finger-shaped egg cases containing about 200 eggs. They lay their eggs next to or attached to each other on the bottom, so that it is quickly covered with thousands of the clustered egg cases. Then both males and females die, so there is no parental care of the eggs or the hatchlings.

Squid are surprisingly difficult to care for. Only a few species have been kept in captivity and even fewer have been raised from an egg. Being open-water animals they are not accustomed to walls, and collide with them when startled. The practicalities of keeping this interesting group have to be worked out before we can begin to study their behaviours in the laboratory. Although there are some shallow-water squid, some members live far deeper and have related adaptation, such as large eyes and photophores (light-producing organs), possibly for luring prey, signalling to each other, counter-shading or perhaps startling potential predators. Some use ammonia in their tissues for flotation since this is more buoyant than water. We also know little about the giant squid living in the depths. These can reach 18 m in length and weigh more than 200 kg, making them the largest invertebrate. Giant squid are the main prey of sperm whales, which are adapted to dive deep to catch the squid, proving that there must be plenty of them in the depths, yet we have yet to see a living giant squid.

A side-branch of the squid family - the bobtail squid - is now providing us with an opportunity to study cephalopod behaviour. Several species live in relatively shallow water, but the majority of the 50 species live on the bottom in deeper waters. Although commonly called squid, these sepiolids bear little resemblance to the true squid. Most sepiolids live on the bottom, where they bury themselves during the daytime and come out at night to feed or look for mates. They are weak swimmers and have a rounded, stubby body ill-suited for fast swimming. They keep their tentacles in a pouch except when used for catching food, mostly small shrimp. They are easily kept in aquariums and many have been reared in captivity from their large eggs. One species, the endemic Hawaiian dumpling squid, is associated with a commensal, light-emitting bacterium. It uses this light-producing ability on its underside to eliminate its silhouette from below when swimming - a form of countershading.

Once buried, a stubby squid may exhibit another interesting behaviour: it may poke the arm tip of one of its second pair of arms up through the sand and wiggle it. This has been described as an angling behaviour. Squid, octopus and cuttlefish have all been described using this behaviour, so it may be conserved across the subclass.

Octopus

Octopus fossils have been dated to as far back as 65 million YBP. Octopuses have just eight arms and no tentacles, hence their name. There is some controversy over the plural of octopus, with octopi, octopods, octopodes and octopuses all used. Shallow-water octopuses have colour-changing ability and use it for the same reasons as cuttlefish and squid. Although octopuses are known for eight-armed crawling, they can also swim, using their funnels for water jet propulsion. However, they cannot swim very far, since they go into oxygen debt while swimming. Usually, they only swim far enough to elude a predator and camouflage against the bottom.

Octopuses mate in two ways, depending on the circumstances. The male mounts the female or extends a modified arm from a distance into her body, passing a spermatophore into her. She can store sperm for several months and then uses it when she lays her typically rice-sized eggs. Eggs of most species hatch

into tiny octopuses that live in the plankton for 1-2 months before settling to the bottom. Some octopuses have larger eggs that hatch out into miniature octopuses that immediately take up a benthic existence. Very few of the smallest species have been reared from an egg.

Sub-adult and adult octopuses are fairly easy to keep in aquariums or research laboratories, with some cautionary provisions. Octopuses are able to escape their enclosures - as primates can. Their escape abilities have achieved legendary status, as many public aquariums can attest to. The common legend goes that an octopus crawled out of its tank, crawled into another tank and ate its occupants, then crawled home, leaving its keeper befuddled on discovering the missing prey. This urban legend is actually based on fact, as an octopus kept at the Brighton (UK) aquarium in the late 19th century crawled out of its tank at night to consume lumpfish kept in an adjacent tank.

Octopuses take well to standard aquarium conditions and water quality, with the exception of exposure to heavy metals, which are toxic. They are extremely susceptible to trace

P.93

amounts of copper, which affects their behaviour. One copper penny in a 60-l tank was enough to affect one researcher's octopus. Octopuses can learn in target training, run mazes and even open jars to obtain food, but much is yet unknown about how they use their intelligence. Their remarkable ability has resulted in them being afforded the same level of protection as vertebrates in some national legislation.

(RCA)

Chemical communication

Chemical communication is ubiquitous among many invertebrates - particularly insects - nearly all vertebrates, including some birds, and bacteria. Chemical communication probably evolved as animals were able to use digestive exudates and secretions from their integument to provide 'honest' signals about the location and features of the identity of the donor to its audience. Chemical communication differs from other forms of communication in that the donor does not have to be present for its message to be read, and chemical signals can persist in the environment.

As many terrestrial animals move about their home ranges they are surrounded by scent marks - some are their own and some are those of conspecifics. Animals investigating these scent marks can often determine many features about the individual that deposited them such as its sex, age, reproductive condition, diet, etc. These scent marks provide a signpost or bulletin board for the transfer of information between individuals. After gathering such information about the signaller, an individual may respond to these scents by seeking the signaller, avoiding it or altering its own behaviour in some fashion.

One type of olfactory communication is scent marking. Scent marking is ubiquitous among terrestrial animals. A current model of scent marking suggests that scent marking serves multiple functions; some functions are unique to each species, whereas other functions serve a general purpose across species, indicating one's presence in an area. This model provides several hypotheses. One hypothesis is that scent marking provides a chemical résumé of the signaller, which may include information about features of its identity. Another hypothesis is that scent marking provides a chemical résumé that accurately reflects current features of the signaller. A prediction of this hypothesis is that scent marking provides 'cheat-proof' signals. A third hypothesis is that animals match the scent marks with their signallers and use this information to distinguish between familiar and unfamiliar individuals, residents and intruders, dominants and subordinates, reproductively active and reproductively quiescent, opposite-sex conspecifics, adults and juveniles, related and non-related conspecifics, and other possible relationships. The last hypothesis of the model is that scent marking is a sexually selected trait used by individuals during same-sex competition and mate choice. A prediction of this hypothesis is that scent marking provides benefits to the signallers and their audience that increases their fitness relative to those individuals that did not

scent mark or respond to scent marks. That is, the benefits of providing olfactory information to conspecifics outweigh the costs of being detected more easily.

Recent work has identified two specialized forms of scent marking, over-marking and self-grooming. Over-marking occurs when animals deposit their scent marks on top of or in close proximity to the scent marks that were deposited by a conspecific. The bulk of the data suggest that over-marking is akin to a modified bulletin board. The bulletin board allows the top- and bottom-scent donors to provide information to conspecifics, but the transfer of information to conspecifics generally favours the top-scent donor of the over-mark. That is, after investigating an over-mark, individuals often spend more time investigating the mark of the top-scent donor than that of the bottom-scent donor when the two marks presented separately. Studies have reported that animals have the capacity to distinguish between the top-scent mark and the bottom-scent mark, including areas in which the positions of the top- and bottom-scent donors change. These studies show that individuals behave as if the top- and bottom-scent marks of an over-mark are distinct, but that the top-scent mark has somewhat greater intrinsic value relative to the bottom-scent mark.

Such findings led to many hypotheses that surround the potential advantages to the top-scent donor of an over-mark that are not enjoyed by the bottom-scent donor. The first hypothesis is that the top-scent mark 'behaviourally' masks the presence of the bottom-scent mark. That is, individuals exploring an over-mark later respond selectively toward the mark of the top-scent donor relative to that of the bottom-scent donor. The second hypothesis is that over-marking provides an advantage to the top-scent donor but not to the bottom-scent donor in the transfer of olfactory information to animals investigating an over-mark. The third hypothesis is that an over-mark is an 'honest' signal, which is based on studies showing that dominant males over-mark the scent marks of subordinate males but subordinate males rarely over-mark the scent marks of dominant males.

Another specialized form of scent marking is self-grooming. Many terrestrial mammals self-groom when they encounter odours of opposite-sex conspecifics, suggesting that self-grooming is involved in olfactory communication between the sexes. The self-grooming hypothesis states that individuals can, by self-grooming, alter features of the odours that they produce. Predictions of this hypothesis are that by self-grooming, individuals produce or release odours that are more attractive than those produced by individuals that do not self-groom. Such odours may reduce agonism between the groomer and opposite-sex conspecifics, and/or increase the odour field that surrounds the groomer, making it more likely that it will be detected by nearby opposite-sex conspecifics.

Studies on species of voles suggest a role for self-grooming in reproduction. Sexually receptive voles are more likely to groom in response to odours of potential mates, and males are especially prone to grooming when encountering the odours of sexually receptive females. Sexually mature male voles also self-groom more than do sexually immature male voles when they are exposed to the odours of sexually receptive opposite-sex conspecifics. In addition, self-grooming patterns are also consistent with the mating system of voles. For example, prairie voles, which tend to be monogamous, self-groom more often in response to odours of their mates than they do in response to odours of unfamiliar opposite-sex individuals, probably conveying a message about their willingness to copulate with their mates. In contrast, meadow voles, which are promiscuous, self-groom more often in response to odours

P.94

of unfamiliar opposite-sex conspecifics than they do in response to odours of a previous mate, conveying a message about their willingness to mate with the former. Interestingly, meadow voles and prairie voles do not spend much time self-grooming in response to odours of their opposite-sex siblings, suggesting further that self-grooming may be a form of mate attraction. Overall, meadow and prairie voles adjust the amount of time they self-groom in response to particular opposite-sex conspecifics, which would increase the likelihood of communicating with potential mates.

Chemical communication is an integral component of both reproduction and competition, as well as other aspects of behavioural ecology. Thus, it is not surprising that researchers are beginning to apply knowledge of scent communication to the management of captive animals, particularly in captive breeding programmes. Breeding success can be improved by providing species-appropriate opportunities for chemical communication or manipulating chemical signals to maximize mating opportunities. Because conspecifics and their odours can also induce stress, judicious management of the olfactory environment can also alleviate welfare problems.

Chewing

Chewing (mastication) commences the breakdown of food, lubricates it for swallowing, adds buffers and, in some species, salivary amylase to the ingesta. Chewing of bones as a postprandial activity in dogs seems to have some additional functions that relate to dental care. Chewing may also have a function in dealing with arousal, e.g. mouthing of articles (including toys and bones) is seen as a greeting behaviour in some domestic dogs. Chewing and licking movements are seen in horses during training and have been putatively associated with stress reduction and even attempts to signal to the trainer. However, this a source of some debate since it could also be that these movements simply reflect dryness of the mouth, perhaps as a result of recent adrenaline activity.

Opportunities to chew are frequently inadequate in intensive husbandry systems since bulky, high-fibre foods are unpopular because they require more labour to handle and create more waste after digestion than concentrated rations. Furthermore, concentrated foods are thought to improve productivity or performance by providing readily digested energy sources that can be consumed more rapidly than less energy-dense (more natural) forages. Fundamentally, diets associated with low rates of chewing are implicated in the development of oral stereotypic behaviours and so it is appropriate to emphasize the importance of chewing as a significant element in the normal time budgets of domestic animals.

The amount of chewing per bolus of food, and therefore the time taken before deglutition (swallowing), depends on a variety of factors relating to the physical properties of the food, including its moisture content and size. For example, when fed to horses, hay requires four times as many chews as oats (per unit of weight) and therefore takes four times as long to consume. It has been estimated that a horse foraging exclusively on high-fibre substrates may chew 57,000 times per day, but that this can be almost halved under moderately intensive stable conditions, e.g. by a 500 kg horse on 5 kg of forage and 7.8 kg of concentrate. This reduction in daily chewing has a profound impact on salivation which, in horses, occurs only in association with mastication and not in anticipation of a meal. So, the chief consequence of feeding less fibre is that there is less chewing and less saliva generated. Since the buffering effects of bicarbonate are diminished under these circumstances, gastric acidity rises and the risk of gastric ulceration increases. The addition of chaff, a traditional means of increasing the time taken to consume concentrated feeds, works simply by increasing the total forage content of the ration. Horses and farm animals on low-fibre diets often supplement chewing opportunities by foraging on straw that has been provided as bedding.

The amount of chewing per day also depends on food availability. For example, free-ranging horses spend an average of 16-17 h/day grazing but, when forage is scarce, they increase their bite frequency and extend the grazing period, sometimes beyond 19 h. Rates of chewing can be increased by reducing the displacement of the lower jaw. That said, the extent to which animals can thrive on poor forage is clearly limited, because they require more energy for ingestion itself. The effect of exercise on chewing is of interest since exercised animals take fewer, but larger, bites than non-exercised controls when grazing.

In all mammalian species, restrictions on feeding behaviour, and especially the provision of discrete concentrated meals that involve minimal chewing, lead to digestive anomalies and behavioural frustration. For instance, free-ranging pigs devote significant portions of their time budget to rooting and chewing. In contrast, intensively managed pigs, fed concentrated foods and given limited access to fibre, can consume their daily ration in less than 1 h and have no normal substrates on which to chew. Various oral stereotypies have been described in tethered sows when not provided with straw. Examples include sham chewing, chain chewing, nipple playing, bar rubbing and bar biting. Inadequate foraging behaviour opportunities are also recognized as potential causes of snout rubbing when pigs rub their snouts on the flanks of other pigs, a behaviour that causes necrosis of target areas.

The timing of discrete meals has an impact on the timing of chewing activity. Nocturnal ingestion naturally punctuates periods of drowsing and sleep and, for this reason, stable managers seeking to reduce the behavioural changes inherent to stabling should leave horses with sufficient forage to last the whole night. In horses, periods without chewing are related to increases in gastric acidity, which predisposes the animal to gastric ulceration.

There is some evidence that chewing by mice may provide some help in coping with adverse stressors and, indeed, hippocampal development (Watanabe *et al.*, 2002). Chewing involves molar activity whereas gnawing involves the incisor teeth. Gnawing in laboratory mice can become stereotypic but is often labelled bar biting. It has been linked to escape attempts.

P.95

Rumination (the circulation of ingested material through the chambers of the stomach, interspersed by regurgitation and further chewing) brings with it a second opportunity to chew fibrous ingesta and can be accomplished in sternal recumbency, so it is an economical means of increasing the energy intake at pasture. Horses devote less time to chewing than ruminants but have to compensate for this by ingesting more food per unit of bodyweight per day. Inability to chew properly as a result of dental problems is one of the chief causes of weight loss in older herbivores and constitutes a welfare problem, especially if mastication becomes painful. Often referred to as broken mouth in aged sheep, this condition is sometimes treated by rasping the teeth, a procedure that is criticized since the evidence for its efficacy is inadequate and there is potential for postoperative chronic pain.

Chewing is sometimes presented as a problem in companion animal behavioural practice. Dogs, especially during puppyhood, readily chew organic substrates. Sometimes this is a natural response to teething and the solution is simply to provide an appropriate target for that behavioural need. Others chew items when left alone as part of a variety of responses to separation anxiety. For example, dogs may chew seat belts when left in cars, or may chew wooden doors and their frames when left inside a house. The latter case could be interpreted as an attempt to follow the owner, since the door targeted is often that through which the owner was seen to depart. Clearly, it would be unwise to treat symptomatically dogs that chew when left, without addressing the problem of their inability to cope in the absence of the primary caregiver(s).

Fur chewing and fur sucking are reported as unwelcome ingestive responses in cats (labelled pica). Most commonly seen in exotic breeds, notably Burmese and Siamese, fur chewing is poorly understood but it has been suggested that it may relate to generalized distress, low-fibre diets or even redirected suckling.

Chicken

Domestic poultry of the species *Gallus gallus* are known by several popular names. 'Chicken' is a generalized term, similar in usage to 'cattle', that may refer to one or a group of adult birds of either sex and to egg layers or meat birds. More often the word chicken is associated with specially bred strains of birds that are termed broiler chicken(s) or just broilers and are used for meat production. The word hen refers specifically to mature females that lay eggs. Cockerel (or cock) frequently is used for mature males but occasionally can be used to describe young birds, for example an all-male flock of broilers. Young female birds are termed pullets when they are intended for egg production: the term is seldom used to describe female broilers. For the first few weeks after hatching young birds are known as chicks, and according to their destiny may additionally be described as either as layer chicks or broiler chicks.

All chicken are descended from the red junglefowl native to the tropical forests of South-east Asia. Junglefowl are omnivorous and spend much of their daylight hours in small groups of typically six to ten adults, seeking food, scratching and pecking in clearings, showing preference for insects and worms but also eating seeds and grasses. They are good flyers and at night roost high in trees to avoid predators. Females lay eggs in clutches of about 12 and then brood them, taking care to select a suitable nest site and to create a nest hollow with materials such as dried grass and a few feathers. Their characteristic pre- and post-laying behaviour routines are recognizable in current commercial hybrid hens, even in the absence of a nest site or suitable nesting materials. Despite hundreds of years of domestication and very intensive selection since the late 1950s, modern chicken retain many other instinctive behaviour patterns of their junglefowl ancestors, such as dust bathing, which is important for maintaining the feathers in good condition.

Apart from farmed fish, chicken are the most numerous, intensively bred and raised species of all farmed animals. Genetic diversity is low among the majority of birds that are commercially farmed, with only a few strains of egg layers or of broilers to be found in significant numbers worldwide. Relatively minute numbers of *G. gallus* remain genetically diverse as backyard and show stock. Commercial flocks are intensively selected hybrids with phenotypic uniformity. Broilers have been selected principally for rapid growth and high feed conversion efficiency, and to have white feathers and relatively large breasts. Layers have been selected to lay continuously rather than in batches and to lay large numbers of eggs, also with a high feed conversion efficiency. Broodiness has been selected against. According to consumer preference for eggshell colour, both white- and brown-feathered strains of hen are common and these lay white or brown eggs, respectively.

The sheer numbers of chicken needed to satisfy the growing demands of an expanding human population of approaching 7 billion is astonishing: over 50 billion broiler chickens are reared per year and some 54 billion t of eggs are produced worldwide. The world population of chickens is estimated by the Food and Agriculture Organization (FAO) to be about 16 billion at any one time, and this includes the large number of breeding birds needed to produce the broilers and layers.

Chicks

There is concern about the exposure of newly hatched chicks to the toxic sanitizing chemical formaldehyde routinely used in hatcheries. Although chicks may be handled automatically on a series of conveyors, separators and counters, generally they are not physically damaged. The method used to kill unwanted male chicks of layer strains varies. In practice, maceration is humane and cost effective despite appearing unattractive. Operators routinely drop chicks into a bin filled with carbon dioxide, which is a heavy, acidic gas. This is a slower method of killing chicks that they find more aversive, but enables whole birds to be sold as feed for birds of prey and other markets. Chicks have yolk sac reserves to sustain them, but performance is reduced if they are transported for long periods or do not feed quickly on arrival at the farm. They need to be transported in environmentally controlled conditions as they do not have well-developed body temperature control systems.

P.96

Layers

Chicks are normally reared by specialist pullet farmers to 'point of lay' (POL) at 18 weeks of age, when they typically weigh 1.4 kg. They are then sold and transported to separate laying accommodation. Floor rearing tends to predominate, but chicks may be reared from 1 day old in cages. Pullets receive several vaccinations during rearing. Research has shown that it is very important that pullets experience features such as perches and nestboxes during rearing if they are to successfully use them in their laying house. Lighting is crucial as it influences age of maturity as well as egg size and numbers. Chicks have up to 24 h of light for the first few days to enable them to locate their food and drink easily and to feed frequently. Many lighting patterns are used but, in general, the number of hours of light per 24 h is first reduced and then increased from about week 16 to stimulate early maturity and ovulation (a step-down-step-up programme). Both during rearing and especially in lay, practical experience has found that low light intensity (< 5-10 lux) can reduce feather-pecking and cannibalism. More recent research has shown that poultry may prefer brighter light for behaviours such as feeding and that ultraviolet light is important for bird recognition and mate selection. Normal tungsten and fluorescent lights do not provide ultraviolet wavelengths.

From a welfare perspective there tends to be some trade-off between meeting the health and the behavioural needs of layers. The prevalent housing system is the wire battery cage, each holding three to five hens and arranged in several tiers. Compound feed such as pellets or mash is provided continuously in a trough outside the front of the cage, and water is accessed via nipple drinkers in the side of the cage. Abrasion of neck feathers from accessing feed is common. The battery cage system has been criticized for inadequate space allowance and for the inability of birds to perform behaviours that experiments have shown to be important to them, such as nesting and dust bathing (see Baxter, 1994). Most current strains of layers are prone to social stress leading to feather pecking and cannibalism. In an effort to control these problems, birds are routinely beak trimmed. Such problems can be worse in systems that allow birds more space and to be kept in larger groups than can establish a stable 'peck order', which is thought to be about 100 birds. Infestation with parasites such as coccidia and red mites is much more likely in non-cage systems that enable an extended behavioural repertoire.

By selecting for improved feed conversion efficiency, the size of hens has been reduced, with adults weighing on average 1.7-2.0 kg depending on strain. There has also been selection for high egg output, and these factors increase the risk of osteoporosis. In non-cage systems over half the population may sustain bone damage and fractures during lay (Wilkins *et al.*, 2004). At the end of lay, osteoporosis renders hens more susceptible to bone fractures, with possibly one in four from battery cages being affected during depopulation. Caged birds suffer disuse osteoporosis from insufficient weight-bearing and wing-flapping opportunities. Modified (or furnished) cages allow more space for exercise and provide a

perch, which improves bone strength (see: **Housing**). Egg production peaks at 90% or more about 3 months after POL and slowly declines thereafter, although egg size tends to increase with age and can be manipulated by altering air temperature (and light). Most hens are slaughtered on economic grounds at 70-72 weeks of age because of the decline in production to about 50%. This compares with a lifespan averaging 7 years in backyard flocks. Some countries permit forced moulting by withdrawal of all feed (and sometimes water restriction), which stimulates egg production for a further 10 months once birds resume feeding. Feed withdrawal is a welfare issue, likely to be aversive and stressful to the hens.

Broilers

The overwhelming majority of broilers are reared from day-old chicks to **slaughter** in a single house on deep litter, which is based on locally available materials such as wood shavings, whole or chopped straw or rice hulls. Even in hot climates, extra heat is provided for young chicks and this is commonly via overhead gas brooders at several points in the house. Powerful single gas heaters can be used to heat the whole house if it is fully enclosed. Chicks usually develop feathers by 4 weeks of age, when controlled-environment house temperatures are then reduced and free-range birds given access to range. Water is usually provided automatically via lines of bell or nipple drinkers. Feeders are hoppers filled manually or via auger - or a trough that runs right around the house with a chain inside to distribute feed. A pelleted, compound ration that is generally based on wheat and soya is used with three formulations - chick starter crumbs, a grower ration that often contains a coccidiostat and a finisher ration for about the last 2 weeks to slaughter. Most broilers are slaughtered at 1.5-2.0 kg at 32-39 days of age. Lighter birds are preferred in a few countries and heavier birds up to 3 kg (7 weeks) are grown for catering outlets and for portioning. Male birds are heavier than females at the same age. Some producers rear single-sex flocks but many are mixed-sex ('as hatched').

The prevalent practice of *ad libitum* feeding of concentrated diets that are high in protein and energy reduces bird viability, and the principal welfare issues in broiler chickens arise from excessive growth rate. Intensive genetic selection has resulted in a proportion of birds within the population that are unable physiologically and metabolically to sustain such rapid weight gain. Examples of metabolic disorders include ascites and heart attacks (flip-overs). Most broilers suffer leg problems to a greater or lesser degree and these essentially relate to the inability of the immature musculoskeletal system to support their weight. With the withdrawal of several antibiotics that were previously in routine use, lameness due to infective agents is now more prevalent and may be the principal cause of lameness in some flocks. Overall, however musculoskeletal disorders predominate. There is evidence that many leg disorders are painful (see Mench, 2004). Many of the conditions have heritabilities between 0.1 and 0.4% and can be selected against.

Breeding companies have selectively reduced the incidence of tibial dyschondroplasia (TD), which is an abnormality of the growth plate in the long leg bone. They have been able to do this by using a lixoscope, which is a portable device that X-rays the legs of potential parent birds to show whether they themselves have the condition. Poor gait is highly correlated with body weight (Kestin *et al.*, 2001), yet it may be possible, by careful multi-trait selection, to improve leg health with little impact on growth rate.

P.97

The incidence of lameness is increased by prevalent husbandry practices such as long light periods and access to feed *ad libitum*, because these do not allow sufficient rest, discourage bouts of activity and encourage excessive eating and hence rapid growth. Manipulating the growth curve by restricting early rates of weight gain and allowing catch-up growth by slaughter age can have welfare and economic benefits. Studies have shown that increased food conversion efficiency resulted in a decreased incidence of lameness and growth-related diseases such as ascites and flip-overs. Lameness tends to increase with

increasing stocking density, and this is thought to be due in part to restricted ease of movement and in part to deterioration in environmental conditions (e.g. air and litter quality).

The most widely used method of assessing lameness is gait scoring, which visually appraises the gait and assigns a score to the broiler's ability to walk. Lamé birds spend less time walking and dust bathing and more time lying than sound birds. They also perform most of their preening and idling when lying and alter their feeding strategy to make fewer but longer visits to the feeder. Broilers are substantially less active than layer or relatively unselected strains of chicken. By selecting for increased food conversion and high growth weight efficiency, it is inevitable that 'lazier' animals are favoured.

Recent estimates of the incidence of substantial lameness (i.e. broilers with a gait score of 3 or higher) in broilers from European surveys range between 2.5 and 30.1%. There is no reason to suppose that these figures cannot be globally applied, which means that between 1.25 and 30 billion broilers suffer with lameness every year. There is a demonstrable need for the incidence of lameness, morbidity and mortality to be monitored in all countries that produce broilers, as economically sustainable losses do not equate with values acceptable for good welfare. Figures from the USA indicate that lameness costs both industry and birds, with leg problems accounting for 1.1% of deaths in production and 2.1% of downgrades and carcass condemnations (Morris, 1993, cited in Mench, 2004).

Growth rate may be reduced by husbandry manipulations such as feeding a less dense diet, meal feeding or reducing hours of light. On the whole a single, long dark period of 6-8 h confers more benefit than short, intermittent light and dark periods. Cannibalism is rare in broilers on a good diet and there seems no justification for maintaining dim lighting below 10 lux - over 20 lux is the recommended level.

Broiler breeders

There are five generations of selection and multiplication involved in the production of broilers. The parents of broilers need to produce a reasonable number of fertile eggs for hatching and thus to live for 1 year or more. Obesity dramatically reduces the fertility of both males and females, as well as reducing their lifespan. All generations of breeders have therefore to be severely feed restricted to prevent obesity, and this restriction leads to frustration, abnormal behaviour and other welfare issues (see Hocking, 2004).

Handling and transport

Catching and handling by humans is an aversive experience for chickens, which have minimal contact with humans during normal commercial rearing. All chicks are handled at the hatchery, where most handling is automated and they are then transported to rearing sites. Limited experimental evidence indicates that, provided transport is of short duration in thermally comfortable conditions, chicks do not experience much stress in transit. Pullets are transferred to the laying house. Not only are they valuable, but they also are metabolically very robust with good feather cover, and hence are resilient to any catching and transportation stressors. End-of-lay hens are metabolically exhausted, osteoporotic and hence susceptible to both cold stress and bone fractures. Broilers have the greatest heat output owing to their high growth rate and good feather cover. They are susceptible to heat stress during transit and lairage. Experimental evidence that birds find the whole transportation experience stressful and fearful is indicated by long periods in tonic immobility (TI) at the slaughter plant. For more details see Weeks (2007).

Chimpanzee

The chimpanzee (*Pan troglodytes*) is one of the great apes, a category that also includes the gorilla, orang-utan and bonobo. There are more chimpanzees in captivity than any of the other great apes. Four subspecies of chimpanzee live in equatorial Africa in a variety of habitats, including subtropical forest, savannah and open grasslands. Captive chimpanzees live in zoos, biomedical research facilities, sanctuaries, and some are privately owned. The behaviour and **welfare** of chimpanzees have been fairly extensively studied. Wild chimpanzees are considered possibly endangered, but certainly vulnerable on the IUCN Red List, with major threats from habitat destruction and hunting for human consumption (the 'bushmeat' trade). Captive populations are in better condition. For example, the chimpanzee population in the zoo community in the USA is considered self-sustaining.

P.98

Wild chimpanzees divide their time between terrestrial and arboreal life, generally moving quadrupedally on the ground, and brachiating and leaping through the tree canopy. They spend about 20% of their waking hours travelling, and generally build elevated nests nightly in the trees. Modern captive chimpanzee housing emphasizes spacious and complex outdoor enclosures, and extensive use of environmental enrichment techniques. Large yards with grass, trees and other foliage, and/or artificial structures encourage physical activity by providing opportunities to brachiate, swing, climb and locomote on the ground. Arboreal sleeping platforms and hammocks are favoured areas, particularly if the chimpanzees have materials for nest building. Chimpanzees should be given a variety of manipulable objects, and they will especially use those that are novel or destructible.

The social organization of wild chimpanzees comprises large multi-male, multi-female groups, with members of all ages interacting in a loosely structured community of 40 to 90 animals or more. Adult males are the social core of the group, and typically (although not always) females transfer out of their natal groups at maturity. Within the large community, there is a fission-fusion structure with smaller parties of chimpanzees, averaging four to eight members, travelling and feeding together, and later reuniting with other members of the larger community and forming new parties. Over the last three decades, more captive chimpanzees have been housed in large social groups, some with over 20 animals, which begin to mimic the species-typical group structure. Living in compatible social groups is the most critical feature in promoting the welfare of captive chimpanzees. Wild chimpanzees are aggressive to chimpanzees outside of their communities, and sometimes fight with them to the death. Aggression is a major issue in managing captive chimpanzees. In a very few cases they have killed one another, but less severe wounding is also of concern. Aggression is especially prevalent during the introduction of unfamiliar chimpanzees and among adult males, although affiliative behaviours typically predominate.

Chimpanzees are long lived, with some individuals living beyond 40 years in the wild and beyond 60 years in captivity. Females typically give birth to single infants after a gestation of about 8 months and have interbirth intervals of several years. The developmental period for young chimpanzees is long - infants nurse and are cared for by their mothers for several years, and are 10-15 years old or more before reaching physical and social maturity. Maternal competence is sometimes a problem, particularly among captive females that were not raised by their mothers and have not lived with infants.

Mother rearing or other forms of early socialization are especially important in facilitating normal behavioural development. It is preferable to allow mother rearing of infants for several years but, if this is not possible, infants can be raised by humans in a nursery. To normalize the development of nursery-reared infants, they should live with other young chimpanzees and they should be introduced to older chimpanzees later in their lives. If infants are raised without other chimpanzees, their behaviour can be disrupted throughout their long lives, including deficiencies in sexual behaviour, maternal behaviour and other social skills, as well as expressing abnormal and stereotypic behaviour. Individual housing of chimpanzees at any age usually leads to behavioural problems and should be avoided if at all possible.

Beyond social housing, many forms of environmental enrichment are effective in promoting the welfare of captive chimpanzees. Some enrichment techniques are designed to elicit behaviours characteristic of wild chimpanzees, and feeding enrichment is an example of this. The diet of wild chimpanzees includes a good deal of fruit, and they also eat a wide variety of leaves, pith, seeds, insects, eggs and meat. Foraging and eating account for the majority of their activity during daylight hours. Tool use is a hallmark feature of this species, and tools are often used in food gathering and processing. Attending to feeding strategies is important in maintaining the well-being of captive chimpanzees. Feeding routines should stimulate long foraging bouts, with multiple meals daily. A variety of foods should be fed that require processing and tool use. Other cognitive challenges can be presented since a variety of food puzzles and devices have been developed for chimpanzees.

Chimpanzees use different forms of sensory enrichment, including watching videotapes and television, looking into mirrors and listening to music. The highly developed cognitive abilities of chimpanzees are well documented, and these abilities should be stimulated by setting problems for chimpanzees to solve. One way to accomplish this is by offering computer tasks, which can be made more challenging over time. Some forms of enrichment give chimpanzees the ability to control their environment or to indicate choices. Choice and control are believed to be important in promoting psychological well-being of captive animals.

Captive chimpanzees' behaviour can be improved by positive interactions with humans. This is particularly important for chimpanzees living alone. Animal training techniques can be used to gain the voluntary cooperation of chimpanzees with routine husbandry activities (e.g. to move within their enclosures on

cue), veterinary procedures (e.g. to examine body parts for wounds or evidence of ill health) and research procedures (e.g. to collect blood or urine samples). Training can address social problems among chimpanzees, such as reducing aggression. Training increases the ease and efficiency in working with chimpanzees, reduces animal distress and is cognitively stimulating. However, the presence and activity of humans can also be a negative influence on chimpanzees. For example, wounding may be higher when there is more human activity around the chimpanzees.

Choice test

A choice test is an experiment in which a subject is required to choose between concurrently available resources or events. Choice tests are used to investigate an animal's motivations and preferences. Here, a 'resource' is defined as a commodity, or an opportunity to perform a behaviour. An 'event' is defined as either a stimulus or an experience such as a husbandry procedure. The term 'preference' denotes a difference between

P.99

the strength of motivation to obtain or avoid one resource or event and the strength of motivation to obtain or avoid another, but also implies that the resources or events are alternatives.

To choose a resource or event, the animal is typically required to move into a chamber in which the resource is located or the event occurs. Since approach is an operant response, choice tests are really a subset of operant tests. Hence, the resources and events that support choice behaviour can be termed reinforcers, or reinforcement, defined broadly as outcomes that motivate animals to perform responses.

Research questions addressed by choice tests include:

(A) To ascertain whether an animal is motivated to obtain or avoid a resource or event, i.e. to ascertain whether it is a reinforcer. We might ask: 'Is bedding material wanted?' or 'Is a particular handling technique aversive?'.

(B) To ascertain whether an animal has a preference among alternative reinforcers. Alternatives satisfy the same positive motivation, or contribute to a common negative motivation. Hence, we might ask: 'Which bedding material is more comfortable to lie on?' or 'Which handling technique is less aversive?'.

(C) To measure the strength of an animal's motivation for a reinforcer, or the strength of its preference between two reinforcers, either in absolute terms or relative to the strength of its motivation for a comparator. When using a relative measure, it is possible to ascertain whether the strength of motivation or preference for the reinforcer of interest is high or low, provided that the comparator is a reinforcer: (i) whose consumption does not influence satiety for the reinforcer of interest, i.e. not a substitute or a complement (this applies primarily to positive reinforcers since it is often assumed that negative reinforcers do not interact); and (ii) that has a known value (e.g. food, electric shock). We might ask:

‘How important is it that the animal has bedding?’ or ‘How strong is the preference for one bedding material over another?’ or ‘How aversive is a particular handling technique?’.

Choice tests designed to ascertain whether a motivation exists (A) operate by giving the subject a choice between the hypothesized reinforcer and a control (no reinforcer). They can distinguish positive reinforcers (in which case the reinforcer is chosen) from negative reinforcers (the control is chosen).

Tests designed to ascertain whether a preference exists (B) operate by giving the subject a choice between two or more alternative reinforcers. They work on the principle that an animal will interact more with a reinforcer it prefers. The choice may be between several positive reinforcers, several negative reinforcers or between positive and negative reinforcers. These tests cannot distinguish positive from negative reinforcers.

In practice, these two types of procedure (A and B) are frequently combined, giving the subject a choice between several reinforcers and a control. For positive reinforcers, the distinction between these procedures may be somewhat arbitrary, e.g. in a choice between a bare concrete floor and a floor with straw bedding, the bare concrete floor would be a control if ‘bedding’ was being evaluated, but an alternative reinforcer if ‘floor substrates’ were being evaluated. For negative reinforcers, the distinction is more robust.

Choice tests designed to measure the strength of motivation or preference (C) are based upon, or similar to, those designed to ascertain whether a preference exists. For positive reinforcers, one important difference is that the reinforcer of interest is compared with a reinforcer that the animal has an independent motivation to obtain or avoid. For negative reinforcers, there is no clear distinction between procedures B and C. Strength of preference (between the reinforcer of interest and an alternative) is assessed if the animal has access to an alternative during the test (in the same location as the comparator), whereas strength of motivation is assessed if the animal has no access to an alternative. These tests work on the principle that the stronger an animal's motivation to interact with one reinforcer compared with another: (i) the more it should interact with one compared with the other; or (ii) the more it should be prepared to give up or work for one compared with the other. Approach (i) is procedurally similar to tests designed to ascertain whether a preference exists (B); however, the validity of this approach is limited when comparing positive reinforcers that satisfy different motivations. Approach (ii) is more complex and has been developed to overcome these limitations.

Specific procedures

The procedures listed below are those that have been used by ethologists. The letters and numbers in parentheses indicate the research questions that have been, or could be, addressed by each procedure. The ‘index’ is the rule used to infer motivation from behaviour.

1. Discrete choice (A, B, Ci/ii). The subject is given one or a series of discrete choices between two or more locations (e.g. chambers, arms of a **T-maze** or **Y-maze**) containing either a reinforcer of interest or a comparator, or no reinforcer (control). *Index*: if the site of the hypothesized reinforcer is chosen more/fewer times than the control location, or by more/fewer subjects, then a motivation to obtain/avoid the reinforcer exists (A); if one location is chosen more/less often, or by more/fewer subjects than another, then motivation to obtain/avoid the reinforcer in the former is stronger (B, Ci). If subjects receive only one test trial each, or widely spaced trials are used (ensuring that only one option is chosen), then this procedure can ascertain whether subjects are prepared to ‘spend’ the comparator on the reinforcer of interest (Cii).

2. Discrete choice, varying the quantity of the comparator (Ci/ii). The subject is given a series of discrete choices between one location containing the reinforcer of interest + quantity X of a positively valued comparator (e.g. food) and another location containing no reinforcer of interest + quantity Y of the

comparator (X or Y may be zero). The ratio X: Y may be varied between trials. *Index*: if the location containing the reinforcer of interest is chosen more/less often, then motivation to obtain/avoid this reinforcer is stronger than the motivation to obtain the quantity, Y-X or X-Y, of the comparator (Ci). If widely spaced trials are used and X:Y is varied between trials, this procedure estimates how much of the comparator the subject is prepared to spend on the reinforcer of interest (Cii).

P.100

Limitations: procedures C1 and C2. When comparing positive reinforcers that satisfy different motivations, the following limitations apply. (i) Non-exclusive choices (where subjects allocate some choices to reinforcer X and some to reinforcer Y) may be difficult to interpret when multiple choices are permitted in a short time period (massed trials), since motivational strength may be confounded with the number of bouts required to reach satiation. *Solution*: use widely spaced trials. (ii) Because sessions tend to be short, this procedure is particularly susceptible to bias caused by fluctuating internal/external variables. *Solution*: see General limitations, below.

3. Free choice: allocation of time (A, B, Ci). The subject is allowed to allocate a fixed amount of time between two or more chambers, containing either a reinforcer of interest or a comparator, or no reinforcer (control). *Index*: if more/less time is spent in the chamber containing the hypothesized reinforcer than in the control chamber, then the subject is motivated to obtain/avoid the reinforcer (A); if more/less time is spent in one chamber than another, then motivation to obtain/avoid the reinforcer if the former is stronger (B, C).

Limitation: procedure C3. When comparing positive reinforcers that satisfy different motivations, motivational strength is confounded with the time required to reach satiation. *Solution*: none.

4. Free choice: change in allocation of time, negative reinforcers (A, B/Ci). The subject is initially allowed to allocate a fixed amount of time between two chambers that may both contain no reinforcer, or that may both contain a standard positive reinforcer to encourage entry. The procedure is then repeated one or more times with a reinforcer of interest added to one chamber. *Index*: if the time spent in this chamber declines then the subject is motivated to avoid the hypothesized reinforcer (A); if the time spent in this chamber declines more for reinforcer X than for reinforcer Y, then reinforcer X is more aversive than reinforcer Y (B/C).

5. Free choice: allocation of time between a negative reinforcer and a positive comparator, both continuous properties of the environment, e.g. air quality versus temperature (Cii). The subject is allowed to allocate a fixed amount of time between one chamber containing the reinforcer of interest + the comparator and another chamber containing no reinforcer of interest + no comparator. *Index*: if less time is spent in the chamber containing the reinforcer of interest, then motivation to avoid this reinforcer is stronger than motivation to obtain the comparator.

6. Free choice: comparison of consumption, positive reinforcers (B). The subject is placed in a chamber containing two or more reinforcers (typically foodstuffs or fluids) for a session of fixed duration. *Index*: the reinforcer that is consumed in the greatest quantity is preferred.

Limitations: procedures B1-B6. Non-exclusive choices (where subjects allocate some time or choices to reinforcer X and some to reinforcer Y) may be difficult to interpret, particularly for positive reinforcers. A 90:10 choice might indicate that reinforcer X is preferred, if the 10% choice is merely due to the subject monitoring the alternative environment; and a 50:50 choice might indicate indifference between reinforcer X and reinforcer Y. However, two alternative explanations must be ruled out, as follows. (i) Fluctuation in an internal or external variable may cause preference to change during or between test sessions (see General limitations, below). (ii) Alternative positive reinforcers may have different uses, so the subject is in fact making a trade-off between two preferences, e.g. between a high-energy feed and a high-protein feed, or between a large cage that is preferred for exercise and a small cage that is

preferred for nesting. A preference can only be established among reinforcers that differ along a single motivational dimension (Nicol, 1997). In order to test whether this is the case, the consequences of consuming/interacting with the alternatives should be compared, e.g. the range of behaviours exhibited, to see whether they have different uses. If they do, the resources should instead be compared using a measure of their substitutability, to test how well one substitutes for another with respect to a particular use.

7. Price elasticity of demand, or slope of the demand curve, cost imposed on access, positive reinforcers (B, Cii). The subject is placed in an apparatus consisting of two or more compartments, each containing either a reinforcer of interest, or a comparator, for a session of fixed duration. There are two costs associated with occupying one compartment: the reduced time that remains to be spent in other compartments and a cost imposed on access to the compartment (an operant response, e.g. a narrow gap that must be squeezed through, or a weighted push-door). The access cost is increased across trials and this constitutes an increase in the price of the reinforcer of interest (note that if access costs to all compartments are increased uniformly, this in fact constitutes a reduction in income, not a change in price - see: **Economics of behaviour**). The number of visits to the reinforcer of interest is taken as a measure of demand and plotted against price, using linear regression, to obtain a demand curve (the amount of time spent with the reinforcer, or the quantity consumed, is sometimes taken as a measure of demand instead, but then cost and demand may not co-vary). *Index:* if the absolute slope of this curve, or the absolute slope of a bi-logarithmic plot of the curve (i.e. the price elasticity of demand), is less for one reinforcer than for another, then motivation to obtain the former is stronger. Alternatively, if the slope of the curve for the reinforcer of interest is not significantly different from zero, or if its price elasticity of demand is less than 1 ('inelastic demand'), then motivation for this reinforcer is strong.

8. Price elasticity of demand, or slope of the demand curve, cost imposed on consumption, positive reinforcers (B, Cii). The subject is placed in an apparatus similar to procedure 7 for a session of fixed duration. The cost of spending time in one compartment is the reduced time that remains to be spent in other compartments. The cost of interacting with or consuming the reinforcer of interest may be increased in several ways: (i) by increasing procurement time of the reinforcer of interest (e.g. by burying it in substrate); (ii) by increasing the motivational importance of alternative reinforcers; or (iii) by subjecting the animal to an unpleasant stimulus (whose intensity may be increased across trials) while interacting with the reinforcer of interest. These manipulations constitute increases in the price of the reinforcer of interest. The time spent with this reinforcer ('expenditure') or the quantity consumed ('demand') is plotted against price, using linear regression, to obtain a demand curve (a plot of demand

P.101

against price) or an analogue of a demand curve (a plot of expenditure against price). *Index:* see C7 (a bi-logarithmic plot of expenditure against price is an analogue of the price elasticity of demand).

Limitations: procedures C7 and C8. (i) When income (the amount of time or energy the subject has to spend) is constant, price changes have income effects (Kirkden *et al.*, 2003). This problem can be ameliorated by ensuring that income is high. (ii) Empirical findings suggest that it is not valid to infer a strong motivation from inelastic demand, for two reasons. First, price elasticity of demand is influenced by procedural variables such as reward size and response type and, for a given reinforcer, it can vary widely between studies. Secondly, practically every reinforcer that has been evaluated in an operant test exhibits price inelastic demand. This is likely to be an artefact of the methodology of operant tests. Therefore, a comparator should be used to assess the relative, not absolute, strength of motivation.

9. Income elasticity of demand, or slope of the Engel curve (describing how demand changes as income varies), positive reinforcers (B, Cii). The subject is placed in an apparatus similar to procedure 7. The cost of interacting with all reinforcers is increased by reducing the session duration. The smaller the session duration, the more costly it is to spend a given amount of time interacting with one reinforcer, because less time remains in which to interact with the others. This manipulation constitutes a reduction in the

subject's 'income'. The time spent with the reinforcer of interest ('expenditure') is plotted against income, using linear regression, to obtain an analogue of an Engel curve (which is a plot of demand against income). *Index*: see C7 (a bi-logarithmic plot of the curve is an analogue of the income elasticity of demand). *Limitation*: procedure C9. This procedure yields relative, not absolute, measures of motivation, since when income is limiting the sum of all elasticities must be zero.

Limitations: procedures C7 to C9. (i) Cost and reinforcer use may not co-vary (Mason *et al.*, 1998). For some reinforcers, the subject may be able to compensate for fewer visits (C7), or for reduced consumption/interaction time (C8, C9), by increasing consumption/interaction time on each visit (C7), or increasing the consumption/interaction rate (C8, C9). Motivational strength will then be confounded with ability to compensate. One solution that addresses the problem in C7 is to place a limit on consumption/interaction time, although this may devalue some reinforcers. A more general solution is to employ these procedures only with reinforcers and comparators for which little or no time (C7), or rate (C8, C9), compensation is exhibited. (ii) Motivational strength depends on deprivation level. When a single measure is extracted from a demand curve, this represents motivational strength at an average level of deprivation, which is of limited practical value (Kirkden *et al.*, 2003). There is no solution to this, although the consumer surplus could be used instead (see: Operant test), (iii) Motivational strength is confounded with the rate at which subjects satiate for a resource as they earn more (Kirkden *et al.*, 2003). Again there is no solution to this other than to consider using the consumer surplus instead. (iv) Motivational strength is confounded with the quantity consumed/interaction time when cost is low (Kirkden *et al.*, 2003). To solve this it is necessary to factor out this quantity/time in the analysis.

General limitations (all procedures)

1. Motivation/preference depends on context. It may be influenced by both external variables (e.g. ambient temperature, group size) and internal variables (e.g. reproductive status). An unchanging context may bias motivation/preference, while a fluctuating context may cause motivation/preference to vary during the experiment, possibly resulting in non-exclusive choices. It is therefore important to check for a correlation between preference and time or context. If this is an important factor, then it can be addressed by measuring motivation/preference separately at a range of different times/contexts.
2. Motivation/preference depends on experience. Animals tend, at least initially, to prefer environments that they are used to. Therefore subjects should have experience of all alternatives before testing, or else motivation/preference should be measured separately in subjects with a range of past experiences.
3. Motivation/preference for positive reinforcers depends on the availability of substitutes and complements, both during and between test sessions. Therefore, experimental reinforcers should not be available between sessions (a 'closed economy'), and the range of other reinforcers available in the test environment should be as similar as possible to the range available in the real-life environment, to ensure external validity.
4. Motivation/preference for positive reinforcers is influenced by the presence of cues emanating from/associated with test reinforcers at the location where choices are made (Warburton and Mason, 2003). Strength of motivation/preference measured in the test environment may therefore not reflect the strength of motivation/preference in the real-life environment. If the real-life environment lacks the reinforcer of interest, or the comparator, then cues should be reduced or eliminated and choice tests should be complemented by behavioural/physiological measures of frustration obtained in the absence of the reinforcer of interest.
5. Measures of motivation/preference do not reveal what is good for welfare in the long term, and so choice tests should be complemented by long-term welfare comparisons between environments that contain, or lack, the reinforcer of interest.

General advantages

1. Choice tests allow animals to express their own priorities, revealing what is important to them (Dawkins, 1990).
2. They are highly sensitive to differences between reinforcers (Rushen, 1990).
3. They can compare widely different reinforcers (Rushen, 1990).
4. They are better able to quantify motivational strength than measures of frustration, since it is unclear how much abnormal behaviour or physiological stress must be shown before motivation can be said to be strong (Dawkins, 1990).

Cholecystokinin

Cholecystokinin (CCK) is a hormone found within the brain and gastrointestinal system that has diverse roles in **sexual behaviour**, learning, pain and, most importantly, gastrointestinal (GI) function and feelings of satiety. Cholecystokinin originates as a prehormone consisting of 115 amino acids, though following further processing can be found in many forms, including CCK-58, CCK-33 and CCK-8. The

relative potency of each form varies with location and species (Reeve *et al.*, 1994). Typically, plasma CCK concentrations will rise within 15 min of a meal's initiation, peak after 30 min then fall to basal concentrations over 3-5 h.

Cholecystokinin is secreted by I-cells of the duodenum in response to the sensation of dietary fat and proteins. Positioning of I-cells allows for rapid detection of intestinal products, and subsequent CCK release into the bloodstream and surrounding tissues. Cholecystokinin affects GI function and secretory products through activation of enteric CCK receptors and stimulation of afferent vagal nerve fibres. The vagus nerve integrates a variety of other stimuli, i.e. other hormones and gut distension, and relays a signal of satiety to the hindbrain and forebrain (Moran and Schwartz, 1994). Cholecystokinin is believed to act synergistically with these other stimuli in generating feelings of satiety.

The effects of CCK on GI function include gallbladder contraction and subsequent release of bile, secretion of pancreatic enzymes and inhibition of gastric emptying.

Cholecystokinin will also have potent effects on feelings of satiety which, when strong enough, terminate feeding behaviour. Gibbs and Smith (1973) first demonstrated a reduction in the size and duration of a meal by exogenous CCK administration. Subsequent studies have confirmed this role, utilizing a variety of species and test procedures (Moran and Kinzig, 2004). Due to a relatively fast-acting nature and short duration of effect, CCK is believed to serve the primary role of ensuring the body does not overload itself nutritionally versus the induction of long-term satiation (Moran and Kinzig, 2004).

Christianity

Christianity, rooted in Judaism and influenced by Hellenistic philosophy, has been the leading belief system in Europe since the early Middle Ages. As such, Christianity became, and still is, an integral and essential part of Western culture and moral thinking. A variety of perspectives regarding human-animal relations met within these three traditions, whereby no single view developed. Rather, within Western culture two lines of thought can be found: one stressing human superiority, the other pointing to human interdependence with creation. The Bible is open to both interpretations.

Humans being described as created in God's image, *Imago Dei*, is a central idea within the Judaeo-Christian tradition. 'Let us make man in our image, after our likeness' (Genesis 1:26). Even if there is no single interpretation of this bible quotation, its basic importance for a Christian belief system is undisputed. The most influential line of thought points at human superiority and rights to use animals for human purposes. This view is mostly taken for granted within Roman Catholic and Protestant Christianity today. Motivated by *Imago Dei*, animal experimentation, animal slaughter for human food and extensive breeding of farm and companion animals has become a widely accepted and common practice throughout Christian cultures. The medieval theologian Thomas Aquinas (1225-1274), the most influential Catholic scholar, motivated human superiority by theological and philosophical arguments. He divided humans from animals, arguing that human rationality showed his closeness to God. Irrational beings have no fellowship with human life, nor can they be friends of humans, since without rationality they cannot be wished good things. Care for animals, however, was still an issue for Aquinas. They should be used 'in conformity with the divine purpose, in order that they may not bear witness on us in the Day of Judgement'. For Aquinas, good care for animals was instrumental only to human eternal life, even if animals will share eternal life. However, according to Celia E. Deane-Drummond's recent Aquinas interpretation (2004), a good Christian becomes a responsible co-creator through treating animals in line with the cardinal virtues.

During the Renaissance human intellectual skills were idealized, and a growing interest in scientific knowledge during

P.103

the Enlightenment led to increased stress on human rationality and their higher moral status. This was in line with theological interest, since the interpretation of *Imago Dei* in terms of human dominion was a means to avoid paganism and pantheism. In mainstream philosophical and theological writings the perspective described so far was the dominant line of thought.

However, this was not without criticism. One famous opponent was the German theologian and physician, Albert Schweitzer (1875-1965). In an acid remark he stated that philosophers and theologians had swept animals out of their theories as efficiently as a housewife kept her doorstep clean. According to this critical perspective, i.e. the interpretation stressing human interdependence with creation, humans have responsibilities towards the rest of creation exactly because they are an 'image' of God. Contemporary theological criticism of human dominion and its practice has a rich tradition of theological writings and arguments on which to build. For example, church fathers such as St John Chrysostom (4th century) emphasized human ability to feel compassion with animals thanks to a close relatedness between humans and animals: 'Surely we ought to show (other species) great kindness and gentleness for many reasons, but above all *because* they are of the same origin as ourselves' (Hume, 1962). Perhaps Christianity would have reacted with less indignation to Darwin's idea of fellowship between humans and other animals if Chrysostom's view had been predominant in theological writings.

St Basil of Caesarea (also 4th century) goes one step further by emphasizing human interdependence and interaction with the rest of creation: 'O God, enlarge within us the sense of fellowship with all living things, our brothers the animals to whom Thou gavest the earth as their home in common with us'. (Hume, 1962). In St Basil's liturgy Christians ask for forgiveness for being cruel towards animals - without a second thought for eternal life. Rather, his prayers are a very early expression of animals seen as valuable in themselves. St Basil's position has strongly influenced Eastern Christendom, and there is a direct connection to today's Orthodox liturgy. Expressing his holistic perspective blessing of creation and creatures is still part of a service. This is foreign to Western Christendom, in which animals and other parts of creation are largely excluded from the liturgical agenda. However, during the end of the 20th century, animal services came into fashion within both Catholic and Protestant Churches. Pet owners, farmers and zoo employees bring their beloved ones to a service where clergy bless the animals. This is

often performed on 4 October, the feast day of St Francis. According to tradition, St Francis of Assisi (c. 1182–1226) showed great compassion and had a humble relationship with animals.

A central issue in animal theology is the question of immortal soul. In traditional Christian interpretation eternal life is reserved for humans, but even here different positions flourish. Perhaps surprisingly for some, Martin Luther (c. 1483–1546) considered the possibility that humans would meet animals in eternal life. There might be differences in the type of souls or immortality, but he did not deny the possibility, and rather regarded it as probable. More explicitly, the Spanish mystic St John of the Cross (1542-1591) argued in favour of animals' immortal souls and God blessing every animal. He pointed at the community of God the Creator with humans and animals, which are created and 'clothed in beauty' in the image of God. He thus extended the concept of *Imago Dei* to include also non-human animals. Other famous Christians arguing that animals have an immortal soul - and therefore should be treated well - were James Fox (1624-1691), James Butler (1692-1752) and John Wesley (1703-1791). Alexander Pope (1688-1744) took a contrary position when denying immortal souls in animals. He emphasized, however, that we ought to treat them with great compassion because they would not be compensated for the cruelty they had experienced in this life.

In contemporary discussions on animal theology the British theologian Andrew Linzey is well known. By relating to some of the above-mentioned theologians he refutes criticism from philosophical animal ethicists such as Peter Singer and Ursula Wolf that Christianity would support any use of animals. Rather, 'the uniqueness of humanity consists of its ability to become the servant species' (Linzey, 1995). Through his 'generosity paradigm' and from an ideal of following Christ, Linzey argues that all marginalized beings, including animals, are objects of direct moral concern. Moreover, due to their dependency and weakness they deserve greater respect than stronger beings, i.e. most humans.

Circadian rhythm

Biological rhythms are probably of universal occurrence in animals, and it is usually easy to demonstrate adaptive explanations for them. They occur in periodicities that range from several seconds to several years but generally, however, there are four common types: circadian rhythms, **diurnal rhythms**, **ultradian rhythms** (over a shorter time period than a circadian rhythm) and infradian rhythms (over a longer time period than a circadian rhythm). Circadian rhythms have a period of approximately 24 h and are primarily endogenously regulated but may be entrained by exogenous stimuli, e.g. photoperiod. In humans, for example, the sleep-wake cycle

P.104

has an endogenous periodicity but it normally becomes entrained by the light-dark (day-night) cycle. Similarly in domestic pigs, circadian rhythms or patterns in body temperature usually cycle around the onset of activity in the morning, but feeding and alterations in feeding times can be used to manipulate its periodicity (Ingram and Mount, 1973).

The area of the **brain** that is central in maintaining circadian rhythms is the suprachiasmatic nucleus, which is situated within the **hypothalamus**. It is located just dorsal to the optic chiasm and receives exogenous light signals through the retinohypothalamic pathway. Other signals originating in the thalamus, midbrain, hippocampus and pineal gland are also capable of exhibiting some regulatory functions. Likewise, there are many neurotransmitters involved in the coordination and expression of these rhythms including adrenaline (**epinephrine**), **serotonin (5HT)**, **acetylcholine**, melatonin and **dopamine**. Disruption of the synthesis and/or release of these transmitters may lead to the interruption of circadian rhythms that can be expressed behaviourally, e.g. disturbance of normal sleep-wake cycles or patterns of activity. In diurnal animals, circadian rhythms are for the most part phased to optimize arousal during active and light portions of the day and to induce sleep (e.g. secretion of melatonin) at night. The opposite is obviously the case in nocturnal species.

Circumcision

Circumcision is a surgical procedure referring to removal of a section of the preputial skin of the penis. In the horse, the term circumcision typically refers to removal of a section of the internal preputial skin (see

Fig. C.5). Surgical texts also name this as the reefing procedure or posthioplasty (Varner and Schumacher, 1991). Circumcision surgery in the male horse is medically indicated to remove a section of the internal preputial skin that has been injured or is affected by tumour. It is commonly recommended to remove as little of the internal preputial skin as necessary to avoid painful or inadequate erections and subsequent breeding unsoundness. The rate of return to breeding soundness has not been documented in horses undergoing this procedure.

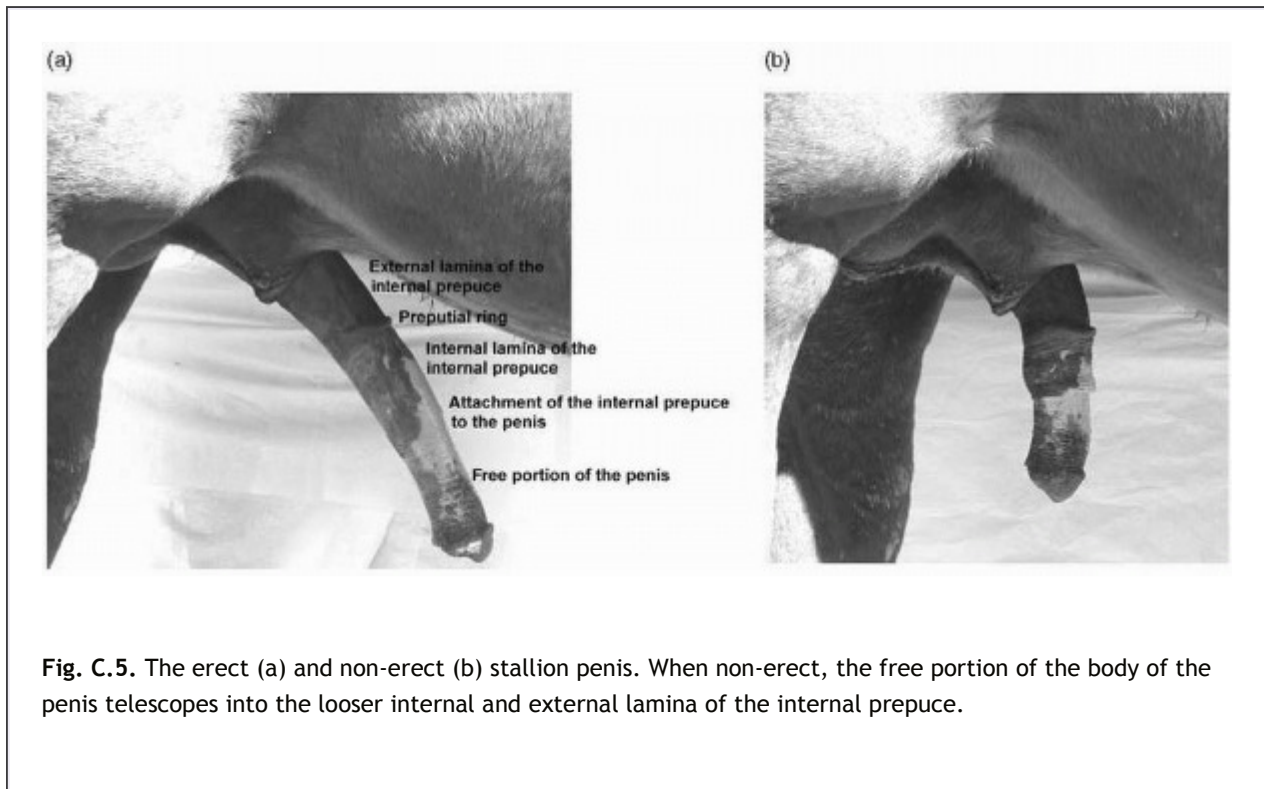

Fig. C.5. The erect (a) and non-erect (b) stallion penis. When non-erect, the free portion of the body of the penis telescopes into the looser internal and external lamina of the internal prepuce.

As in the horse, circumcision in the bull is performed for medical reasons, most commonly to prevent recurrent preputial injuries. Related surgical procedures are also performed to create teaser bulls that are unable to successfully complete intromission. Circumcision has been reported as creating stallions as teasers in a pasture heat detection system (Silva *et al.*, 1994). However, in this case it is not the internal preputial skin but the epithelium of the shaft of the free portion of the penis that is removed, from just behind the glans penis to the attachment of the internal prepuce. Extensive removal of the epithelium, followed by surgical closure of the distal and proximal ends of the wounds, results in an effectively shortened penis and thus the inability to complete intromission. **Sexual behaviour** of the circumcised stallions measured up to 180 days postoperatively was similar to that of uncircumcised stallions and considered adequate to aiding in oestrus detection. Though reported in the literature, this procedure does not appear to be common in practice.

Use of the term 'circumcision' may effect comparisons with the surgical removal of the foreskin (prepuce) in human males. In the human there are gross and histological indications, as well as psychological assertions, that the foreskin plays an integral role in sexual gratification, in part due to its relative mobility even with the penis in the erect state. In the horse the internal prepuce does not appear to have the same degree of mobility during erection and thrusting, though detailed gross anatomical and histological studies have not been reported.

Circus

A circus is an arena (usually round) in which humans and/or non-human animals perform for the entertainment of others. A circus may be a temporary, seasonal or permanent establishment, and may use wild or domestic species. Integral to their use is their training to perform entertaining activities. Very little scientific research has been carried out on the training or **welfare** of circus animals, possibly because of the relatively small size of the industry from a provision perspective (although consumer numbers are high). None the less, concerns can be divided into the following categories: (i) the accommodation of circus animals (see: **Confinement**), when both on the road and in winter quarters (see: **Housing, space**); (ii) the stress of **transport**; (iii) the training methods used (see: **Reinforcement - types of**); (iv) the stress of performance; and (v) the sourcing and dispersal of animals after their working life is ended. The mobile and transient nature of circuses can pose challenges to the enforcement of regulation of standards.

The use of wild animals is of growing concern, although international conventions such as CITES should regulate the sourcing of animals of conservation importance from the wild. However, these animals generally appear less adapted to confinement and may frequently show signs of stress when asked to perform in the arena, although many animals used in circuses may show no evidence of distress and some may appear to show signs of enjoyment. There has been an increased trend in using domestic species (especially horses, cats and dogs) or only human performers in many circuses in recent years as a result. Concerns are certainly justified when animals are asked to perform behaviours that may be biomechanically or physiologically very stressful, e.g. **elephants** balancing on their hindquarters or horses dancing on their hind legs, by which their backs may be hyperextended (see Fig. C.6).

Assessment of the welfare of such animals poses particular challenges. Reluctance to enter an area (including **transport** and accommodation facilities) and observational assessment of physical health and body condition are relatively simple measures of the individual that can be used at least as a preliminary measure, together with an assessment of the physical resources available and management regimes. In some countries, such assessment is a necessary condition for licensing of the circus, while in others little or no regulation exists. One study in the UK found that 70% of animals were not in peak condition, and that coprophagia and stereotypic behaviour were frequently shown by animals when confined (see Figs C.7 and C.8).

Fig. C.6. A circus horse being trained to rear on command. Prolonged or frequent hyperextension of the back can result in musculoskeletal and/or arthritic problems.

Fig. C.7. Restrained circus elephant manipulating faeces prior to ingestion.

Fig. C.8. Restrained circus elephant showing stereotypic weaving behaviour.

It has been suggested that this high prevalence may relate to a genetic influence in the founder population and high levels of **inbreeding** and, while this may offer an explanation, it does not invalidate the primary concern over the welfare of these animals.

It is generally recognized that circuses do not fulfil a meaningful role in animal conservation and their impact on education is minimal; however, their potential in this latter regard is probably underexploited as the science of animal training has developed to the point where they could be used to illustrate the importance of conditioning procedures and good communication in animal training.

Far from being a detrimental stressor, it has been argued that training, and potentially performance, may be enriching for the animal if conducted using appropriate methods, and the value of training as an environmental **enrichment** in zoos is increasingly recognized. However, it has been suggested that, unlike in zoos, where training is used to add environmental complexity and control, the training of circus animals is very repetitive and so potentially less enriching. For some, regardless of the methods used or their educational potential, the concept of an animal circus is rejected on ethical grounds (see: **Ethics**).

Clever Hans

Hans was a Warmblood horse living in Berlin at the turn of the 20th century. His owner, Wilhelm von Osten, was a former schoolteacher. Von Osten, clearly confident of his own teaching skills as well as his horse's intellectual abilities, embarked on the ambitious task of educating Hans to complete cognitive tasks traditionally associated with scholastic exercises for humans. His efforts were rewarded when, after 4 years of training, Hans could demonstrate his seemingly remarkable intellectual abilities. Hans could perform mental arithmetic (add, subtract, divide and multiply numbers), could read and spell, and even answer questions on history, music, literature and geography, extraordinary feats for a non-human animal (though, prophetically, not for a human). Of course, Hans could not speak, but could give answers to specific questions by stomping his hoof. For example, when posed an arithmetic problem Hans would provide his solution by stomping his hoof the correct number of times.

Clever Hans and his owner quickly became famous, and attracted the attention of sceptical scientists, most notably Professor Carl Stumpf, director of the Berlin Psychological Institute. The obvious 'logical' explanation for Hans' abilities was, not surprisingly, that von Osten was giving discrete clues to his horse as to how to respond. These clues could have been given deliberately, in which case von Osten was a fraud, or else he could have been unintentionally providing reactions that reliably cued Hans to the correct answer. However, this theory was quickly shown to be wrong, because Hans still performed remarkably well when posed questions by someone other than von Osten, even when von Osten himself was absent.

Stumpf then enlisted a young German psychologist, Oskar Pfungst, in the task of investigating in detail Hans' remarkable abilities. Hans' answers were indisputably the product of mental calculations or acquired knowledge, and it was natural to attribute these to Hans himself. But, of course, whenever Hans was tested, it was in the presence of humans, and their ability to answer these questions was never in doubt. Was it still possible that the mental processes attributed to Hans were, in fact, being performed by other people present at the same time? Pfungst's insight was to recognize this possible confound and to devise a means of eliminating it. Pfungst's systematic approach has become a landmark in the history of experimental psychology. The critical experiment devised by Pfungst was to test Hans with the only people present being ignorant of the answers to the questions posed. To achieve this, Pfungst and his assistants prepared questions on cards, and these cards were then presented to Hans in a different room. The people present in the room with Hans, including the person holding the cards, could not see the questions written on the cards, and thus could not know the correct answer. Under these conditions, Hans performed badly. Clearly, then, it was the presence of people who knew the answer that determined Hans' performance. That is, people were somehow providing the answers to Hans. But how?

Pfungst and his collaborators were not about to reject one implausible conclusion - that Hans was capable of spelling and arithmetic - and replace it with an even less plausible one - that Hans was capable of mind

-reading. Instead, Pfungst concluded that Hans was exquisitely sensitive to the behavioural reactions of people. That is, small involuntary movements were cues that governed Hans' responses. Pfungst then set about to test his theory and uncover which responses were responsible. Initially, Pfungst fitted Hans with blinkers, and then asked von Osten to stand beside Hans, out of view. Under these conditions Hans performed badly, indicating that

P.107

visual cues were necessary to guide Hans' stomping. Pfungst then proceeded to make careful examination of von Osten's behaviour during each test. What Pfungst noted was that von Osten's posture and facial expression changed subtly across the course of each test. Specifically, von Osten would tilt his head forward, to look down at Hans' hoof, at the commencement of each test, but would lift his head back up when Hans' stomping reached the point corresponding to the correct answer. This latter response was accompanied by characteristic facial expressions - flaring the nostrils and arching the eyebrows. Importantly, these behaviours were not unique to von Osten. In subsequent laboratory studies conducted by Pfungst, 90% of people displayed similar behavioural reactions in anticipation of the correct answer to a question being tapped out by the experimenter. Such findings are a testament as to how uniform across individuals human behaviour can be.

Although these behaviours were clearly correlated with Hans' performance, that alone does not prove they controlled it. It is possible that both von Osten's and Hans' behaviours were determined by the answer to the question posed, or even that von Osten's reactions were in response to Hans' stomping, not vice versa. The clinching evidence came when Pfungst demonstrated that his own postural changes and facial expressions alone were sufficient to control Hans' responses. In the absence of any question posed of Hans, the horse would start stomping and then stop again solely in response to Pfungst tilting his head forward and then lifting it back again. Therefore, von Osten's subtle behavioural reactions were both necessary and sufficient to determine Hans' performance. Thus, it seems, Hans had not learned how to spell or do mental arithmetic, but instead had learned to start stomping his hoof in response to certain behavioural cues, and to stop stomping in response to other behavioural cues.

Pfungst went on to publish his investigations in 1909, in his book *Clever Hans (The Horse of Mr. von Osten). A Contribution to Experimental Animal and Human Psychology*. It should be noted that, before Pfungst's investigations, von Osten himself was unaware of these mechanisms - his own unconscious behaviours provided reliable information to his subject about how to respond.

The story of Clever Hans is an enduring one because it provides several important lessons. First, and most immediately, it highlights the pitfalls in our ability to draw conclusions about the psychological or mental states of other animals based on their behaviour. Hans is a classic illustration of the traps of anthropomorphizing - it is seductively easy to ascribe human psychological processes to explain the behaviour of other animals. A broader lesson concerns the appropriate use of scientific methodology to investigate behavioural processes. Pfungst devised the first test in which the experimenter was naive to the experimental condition (the question posed) and thus to the expected outcome, a procedure at the heart of 'double-blind' testing protocols that have become indispensable in many psychological and medical studies. The explicit lesson here is that animals, including humans, are exquisitely sensitive to picking up what is expected of them by an experimenter and behaving accordingly.

Clicker training

This refers to an application of the principles of positive reinforcement and the use of a secondary or conditioned reinforcer to train an animal to perform behaviours.

Clicker training derives primarily from learning theory, as developed by Skinner and Watson. These theories were applied by animal trainers such as the Bill and Marian Breland Bailey in the mid-1900s and entered first the marine mammal and later the dog and horse training fields, primarily through the writings of Karen Pryor in the 1960s. The name derives from the 'clicker', a small plastic box with a metal tongue, which, when depressed and released, makes a 'click' sound. The sound of the clicker is paired through classical conditioning with a primary reinforcer, usually food, until it acquires the status of a conditioned reinforcer. Once this association has been made, the sound is used to mark precisely the desired behaviour as it is displayed by the animal being trained. Delivery of the primary reinforcer then follows at a convenient interval. In this way the clicker may be referred to as a 'bridge'. As the conditioned reinforcer does not require direct interaction with the animal, it can be used accurately to mark the behaviour upon which the reinforcer is contingent, and so the accuracy of training can be improved and, in some cases, the speed of learning in practice can be increased. Once behaviours have been learned, a cue is then associated with the behaviour and the clicker is no longer needed as the learned behaviour can then be maintained through other forms of reinforcement.

Clicker trainers traditionally make use of other aspects of learning theory, for example shaping new behaviours through successive approximation, although luring of behaviours and capturing of complete actions also are used. Because the technique relies on communicating with the animal without the need for contact, it has been successfully applied to captive wild animals, where it is usually employed to improve husbandry and welfare, for example in training animals to cooperate with handling procedures instead of needing to make use of sedation.

Clinical behaviourist

A clinical behaviourist is a professionally trained individual, a veterinarian and/or a PhD, who assesses and treats behavioural problems of animals, usually domestic animals, but also exotic **pet** and **zoo** animals. The most rigorous training is that of veterinarians who, in many countries, have organized a specialty board. For example, in the USA, in order to be board certified, a veterinarian must have at least 1 year of clinical medical experience and then a 2-3-year residency, during which the major portion of time is devoted to treating animals with behavioural problems. In addition to the residency, the veterinarian must also have published a paper in a refereed journal, must submit three acceptable case reports and take 2 days of written examinations. There is also specialty

P.108

recognition in Europe and Fellowship examination in Australia. The Animal Behaviour Society based in the USA also certifies applied behaviourists. In order to be certified the candidate must be a PhD (or have a Master's degree for certification as an associate), must have taken courses in behaviour, learning, etc. and submit case reports.

The sister organization outside North America has more recently developed a certification programme for graduates elsewhere as Certificated Companion Animal Behaviourists. It requires formal education in a range of topics, supervised experience and case histories, but no postgraduate qualification. Cases can be seen in a clinic setting or in clients' own homes. Most clinical behaviourists ask the owner to describe a detailed history of the problem and the owner's response to the misbehaviour, as well as the general management of the animals. Medical causes of behavioural problems must be eliminated, either by a referring veterinarian or at the time of the consultation. Board-certified veterinarians and clinical behaviourists use behaviour modification techniques and, in addition, the former can prescribe psychoactive or other drugs as required. The most common problems presented to clinical behaviourists are aggression in all species, separation anxiety and fears/phobias in dogs, house soiling in cats and stereotypies in horses.

Clone

A clone is when two or more animals have the same genetic make-up, e.g. like identical twins, but the production is artificially induced (splitting the fertilized egg at a very early stage of fewer than eight cells, or transferring somatic cell nuclei to a fertilized egg that has been enucleated). The latter technique means that the clones are separated in time.

(DBM)

See also: Cloning

Cloning

Somatic cell nuclear transfer or somatic cell cloning is a way of producing another animal of the same genetic make-up as the donor animal. It was originally performed in frogs using intestinal cells as the source of DNA, but has now also been achieved from other somatic cells (mammary gland) and early embryonic cells (four- to eight-cell stage). In some species, e.g. cattle, cloning from somatic cells has been found to cause an exceptionally high incidence of abnormal fetuses (overgrown) but, in other species such as pigs, these problems have not been found. Offspring of the clone do not appear to be affected. Apart from frogs, cloning has been carried out with sheep, cats, cattle, dogs, mice and horses.

Reproductive cloning, when early-stage (e.g. four to eight cells or blastomeres) embryos are split by dividing the blastomeres and inserted into enucleated ova still with their *zonae pellucida*, has been successful, but few studies have been carried out on their **health and welfare**.

Cockfighting

Cockfighting is the pitting of two fighting cocks (roosters) against each other for sport. The fight takes place in a cockpit. The sport is closely associated with gambling, with bets made on the outcome of the match. The cocks are purpose-bred and trained for fighting. Cockfighting is banned in most Western countries, but continues to be a popular traditional blood sport in many Eastern countries. The sport has existed in many cultures, including those of India, China and the Middle East, since ancient times. It was introduced to Greece in the period 500-450 BC, was subsequently adopted by the Roman empire and spread to England, Wales, Scotland, Italy, Germany and Spain and their colonies. While opposed by the Christian church because of its association with gambling, it became a popular sport supported by the English monarchy from the time of Henry VIII. Cockfighting was popular in America from the time of early settlement until after the Civil War, with both Thomas Jefferson and George Washington being supporters of the sport. By the early 1800s the sport had become so well established in Britain that cockfights were regularly held in churchyards and schools.

A cockfighting match usually consists of several fights between birds. The birds are placed in a circular pit about 6 m in diameter, surrounded by the audience. Purpose-built arenas may have tiered seating around the pit. Depending on the tradition, a pair of birds is placed in the pit, or several are placed together (known as the 'battle royal'), until one bird emerges as the overall victor.

Despite its long-term popularity, the cruelty of the sport was recognized by Boswell, as recounted in his London Journal written in 1762:

I then went to the cockpit, which is a circular room in the middle of which the cocks fight. It is seated round with rows gradually rising. The pit and the seats are all covered with mat. The cocks, nicely cut and dressed and armed with silver heels, are set down and fight with amazing bitterness and resolution. Some of them were quickly dispatched. One pair fought three quarters of an hour. The uproar and noise of betting is prodigious ... I was sorry for the poor cocks. I looked around to see if any of the spectators pitied them when mangled and torn in a most cruel manner, but I could not observe the smallest relenting sign in any countenance.

As indicated above, birds sustain severe injuries during fights, including lacerations to the body and eyes, punctured lungs and broken bones. The end of the fight is usually signalled by the death of all but one of the birds, although in some cases a time limit is set or birds may be withdrawn when severely injured. Birds may be fitted with extremely sharp metal spurs or blades, sometimes armed also with rowels (sharp discs on the end of the spur), designed to puncture or mutilate the opposing bird. The spurs are fastened to the bird's leg with a leather bracelet or similar and vary in length from around 3 to 8 cm.

Fighting birds are bred from game fowl, closely related to the Indian red junglefowl (*Gallus gallus*), from which domestic chickens originate. Breeding of gamecocks remains popular regardless of whether or not fighting is banned. The birds are highly colourful and with a distinctive erect stance and long spurs. Fighting birds are exercised when young to build up muscle mass. They are generally fed a high-protein diet and may also be massaged with an astringent solution to toughen

P.109

the skin. Their feathers are clipped and the comb is trimmed to reduce the targets for opposing birds. Training may also include pitting birds against each other while wearing pads over their spurs. Birds are usually put to fight when they are between 1 and 3 years old.

Cockfighting behaviour stems from natural aggression between roosters. However, this is exaggerated in gamecocks through selective breeding and training for maximum aggression. Domestic roosters and their feral counterparts will challenge each other to establish dominance, territory and to gain access to hens, but such encounters are short lasting and rarely result in serious injury. Breeding game fowl has involved

selecting and breeding from the most aggressive roosters to heighten fighting behaviour. This may be further supplemented by the use of pharmacological stimulants (such as caffeine, **epinephrine** or amphetamines) and the use of spurs to increase the injuries resulting from aggressive behaviours. Training to maximize aggression towards other roosters involves isolating the bird from conspecifics to reduce their experience of natural **social behaviours**. This lack of social experience means they have little ability to interpret signals used during male-male conflicts that would generally (in a more natural context) lead to a peaceful resolution of the encounter.

Cockfighting was first prohibited by law in Massachusetts in 1836, and in most other American states it is now expressly banned through specific legislation or is prohibited under general cruelty to animals legislation. The sport was prohibited in the UK in 1849 and, for more than a century, it has been illegal in many other countries, including Australia, New Zealand, Canada and most of Western Europe. In some countries the possession or sale of gamecocks and/or cockfighting spurs, keeping a cockpit, attending or promoting a cockfight or transporting birds for the purpose of fighting are listed as offences under animal welfare legislation. Despite these laws, the sport has continued underground in these countries, with illegal fights a regular occurrence. Gambling at these events is endemic and is based on wagers between individual spectators. Many thousands of dollars can change hands during a match, creating a tense and often violent environment. Cockfighting is often associated with other underground activities, such as illegal firearms and other weapons, illicit drugs and other blood sports such as dog-fighting. Prosecutions by organizations such as the **RSPCA** on cockfighting-related charges are a regular occurrence where cockfighting rings have been exposed or people have been found in possession of cockfighting equipment.

Cockfighting remains a popular legal sport in many places, including Latin America, Africa, South-east Asia, the Philippines and also in some parts of the USA (Louisiana, New Mexico). In some countries there is a close association between cockfighting and cultural or religious rituals. For example, in Balinese culture the ancient Tabuh Rah ritual to expel evil spirits involves three cockfights, each to spill blood on the ground as an offering. Cockfighting is a male-dominated activity and women may be specifically excluded from fights or related rituals. In South-east Asia the sport is so widespread that most men in rural villages will own at least one fighting cock and fights are part of regular village activity.

Codes of practice

Wherever humans use, house or manage animals, there is the potential to cause avoidable **suffering** if the animals' needs are either not understood or not awarded sufficiently high priority. National and international legislation relating to different areas of animal use often includes voluntary or mandatory codes of practice, with the intention of ensuring that animals are cared for appropriately and treated humanely. Codes of practice have been drawn up for many different types of human-animal interaction, including animal housing and care, **transport**, **killing** animals, the conduct of veterinary, husbandry or scientific procedures, breeding and sale. Further information on specific codes of practice can be obtained from national government departments that administer the relevant primary legislation, e.g. Agriculture and Agri-food Canada, the United States Department of Agriculture or the UK Department for Environment, Food and Rural Affairs (Defra).

There is a fundamental need for codes of practice, because they can protect animals from unacceptable treatment or levels of care, but it is important to note that the welfare of animals housed or treated according to a code of practice is not necessarily good. This is because codes of practice are drawn up not only to fulfil animals' best interests, but also to satisfy a range of different stakeholders. These usually include: (i) the regulatory bodies that will be monitoring the guidelines and ensuring compliance; (ii) relevant industries; (iii) animal behaviour and/or welfare societies; and (iv) individuals that will be regulated by and are required to implement the codes of practice. Balancing the different priorities held by each of these groups usually results in standards that represent a compromise position and have a number of functions, such as:

- minimizing or eliminating avoidable suffering;
- improving animal welfare;
- improving animal health;
- encouraging implementation of the spirit of a piece of legislation (e.g. by setting out appropriate environmental enrichment or techniques for humane killing);
- standardizing or harmonizing global practice;
- preventing malpractice that could present a risk to human health or wellbeing; and
- maximizing benefits to humans such as increased productivity, reduced economic costs or improved scientific validity.

Different codes of practice give different weightings to these criteria, depending on prevailing social, political and economic pressures and how these are brought to bear. There will always be conflicts between the needs of humans and animals; for example, optimal animal welfare often requires more expensive housing and higher staffing levels. The economic implications of this may be acceptable for zoos, yet very strongly resisted by sectors that aim to maximize animal productivity and minimize costs. Economic considerations can also result in very different standards within the same species. For example, husbandry guidelines for domestic fowl used in experiments include much better standards than most fowl experience in an agricultural setting, although they relate to

P.110

the same species with the same requirements for basic wellbeing (see Table C.3).

Another possible reason for such discrepancies is that, historically, codes of practice were based almost entirely on perceived good practice within a particular sector at that time. In recent years there has been a rapid expansion of the literature on animal behaviour, **preferences**, **motivation** and physiological responses to different husbandry protocols and events such as **transport**. This is now routinely channelled into new and revised guidelines, but it can still prove difficult to change traditional perceptions on what is acceptable practice. Challenging the *status quo* is, of course, especially problematic for species where empirical evidence is still scarce or non-existent.

Whichever factors have influenced the development of a code of practice, in the majority of cases even recently updated guidelines will represent minimum standards, not best practice. As a consequence, codes of practice can actually prevent proactive welfare improvements if they are implemented to the letter without question. If an individual believes that the legislation regulating his/her activities is strict (which is likely, given that it restricts their actions), he/she will probably also believe that its codes of practice are equally rigorous and promote good welfare. It can be difficult for a regulator or inspector to change this attitude and encourage better practice, especially if he/she is operating in an advisory capacity and has no legal inducements. In some cases, especially for farmed and laboratory animals, there are voluntary, higher welfare standards that can be used to encourage a more animal-centred approach.

One further advantage of voluntary guidelines is that they can be frequently updated to take account of new applications of technology to animals and new information about animal behaviour and welfare needs, whereas official codes are more likely to lag behind recent knowledge and public attitudes.

When considering and assessing a code of practice, it is often very useful to compare it with a range of voluntary standards, and also with equivalent codes of practice in other countries and for animals used in other contexts. Each of the recommended space allowances for laying hens in Table C.3 gives different priorities to animal welfare, but all claim to provide sufficient space for the birds' behavioural needs to be fulfilled. The standards from the two welfare bodies are significantly different, although both aim to set allowances that will improve significantly on current practice yet be attainable for the majority of producers. Evidently, both bodies have made different judgements as to what can feasibly be achieved as a first step towards improving the quality of life of the laying hen.

Table C.3. Comparison of floor space allowances^a within some codes of practice for laying hens.

Organization	Space allowance per bird (cm ²)
United Egg Producers, USA ^b	393 (white Leghorn)
	439 (brown egg-layers)
McDonald's	465
British Egg Industry Council	550
UK Farm Animal Welfare Council	600
RSPCA Freedom Food	855
UK Home Office, laboratory chickens 1800-2400 g (group housed)	1200
Draft revision of Council of Europe Convention ETS123 for the Protection of Vertebrate Animals used for Experimental and other Scientific Purposes, laboratory chickens 1800-2400 g (group housed)	1300

^aThis table lists space allowances only for simplicity, but it is also essential to provide a good-quality environment within the available space.

^b These guidelines apply from 1 April 2005; producers will have had to increase space allowances to 432 cm² for white Leghorns and 490 cm² for brown egg-layers from 1 April 2008 to retain their 'Animal Care CertifiedTM' status.

An ideal code of practice, free from such practical, political and economic constraints, should encompass the principle of a *duty of care* on the part of all those responsible for animal housing, husbandry, use and management. The **five freedoms** concept, as adopted by the UK Farm Animal Welfare Council (**FAWC**), provides a useful basis for defining a duty of care that reflects the basic needs of each species and strain. It was originally set out for farmed animals, but it can be partly or wholly applied in all contexts including **companion, laboratory and wild animals** in and out of captivity. At the time of writing, there is no such ideal code of practice that includes a duty of care, has an entirely objective basis and will ensure good animal welfare. It is therefore vitally important to approach and use all codes of practice critically, review the literature regularly and always implement better practice and/or encourage others to do so.

Cognition

Broadly defined, cognition refers to 'the mechanisms by which animals acquire, process, store, and act on information from the environment' (Shettleworth, 1998). Given this definition, the study of cognition encompasses a wide range of topics, including sensory systems and **perception**, learning and **memory**, **decision making**, navigation, **communication** and **language**, and reasoning. Cognitive processes unquestionably play important roles in behaviour including, for example, the remarkable abilities of honeybees to communicate the location of a food source to their hivemates, crows to fashion tools or Clark's nutcrackers to recall the locations of thousands of cache sites. Our efforts to understand behaviours such as these can scarcely be complete without an exploration of cognition.

P.111

While 'cognition' is often assumed to imply complicated processes leading to declarative knowledge (rather than procedural, or route 'how to' knowledge), a broader definition of cognition is useful because it allows for the possibility that complex behaviours may be governed by relatively simple mechanisms. Such a definition does not, however, encompass issues of **consciousness**. The questions of whether animals are self-aware, understand emotions, have intentions or plan actions are ones that are especially difficult to answer because behaviours that might be motivated by conscious thought can usually be explained in terms that do not require reference to consciousness. While some may disagree, most scientists studying animal cognition use the information-processing definition of cognition and agree that cognition can and should be studied without reference to consciousness.

The study of cognition

Historically, the study of cognition has been pursued independently by psychologists and ethologists. Much of the early research in animal cognition focused on animal learning, and was primarily conducted by experimental psychologists. One dominant idea motivating much of the research in animal learning emphasizes that most learning can be explained by a few general processes. One of the most influential general process mechanisms is associative learning, the process by which animals learn cause and effect relationships and how to respond to them. Perhaps the best-known example of associative learning is

Pavlovian or classical **conditioning**, where animals learn associations between a novel stimulus and an unconditioned stimulus.

In his famous experiment, **Ivan Pavlov** demonstrated that a dog can be trained to associate a sound (a conditioned stimulus, CS) with the presentation of food (unconditioned stimulus, US) and will salivate in anticipation of the food (conditioned response, CR) when it hears the sound (CS). Thus, an association is formed between the two stimuli, the sound (CS) and the food (US).

Another type of associative learning, instrumental conditioning (first described by Edward Thorndike) has also played an influential role in the development of associative theories. In instrumental conditioning, also known as **operant** conditioning, animals learn relationships between stimuli and responses based on the consequences (reward or punishment) of their actions. If the consequence is pleasant, the association between stimulus and response is strengthened and, if unpleasant, the relationship is weakened. For example, rats can be trained to press a lever if that action is followed by a reward such as the delivery of food.

From these basic concepts, associative theory has grown with the core assumption that the formation of associative relationships between two events (stimuli and responses) can explain most learning phenomena. The success of the associative paradigm can perhaps be attributed to a couple of factors. First, research in neurobiology on the formation of synaptic connections has provided a physiological explanation of associative mechanisms. Secondly, models of associative learning have succeeded in explaining many learning phenomena, thereby demonstrating how many seemingly complex behaviours can be explained without resorting to mentalistic explanations. However, associative explanations fail to account for all types of learning, and critics have cautioned against an overemphasis on associative accounts and general process views of learning.

The strong emphasis on general learning processes accounts in part for psychologists' overwhelming reliance on a few species - primarily rats, pigeons and monkeys - in their research. In contrast to experimental psychologists, biologists are guided by an evolutionary framework and recognize that species may differ in their cognitive abilities as a result of differing ecological pressures and evolutionary trajectories. Hence, biologists are interested in studying the cognitive differences in a wide variety of species and are mindful of the evolutionary and ecological factors that create such differences.

The field of **ethology**, the biological study of behaviour that flourished in the mid-20th century, was dominated by European zoologists whose primary concern was to study animal behaviour in relation to their natural environments. One of the founding fathers of ethology, **Konrad Lorenz**, described behaviour patterns as 'organs', specifically adapted to the functions they serve, and focused his studies on species-specific differences in patterns of behaviour. From this tradition, the field of **behavioural ecology** developed with a similar focus on asking functional, evolutionary questions about behaviour and studying a diversity of animals in their natural environments.

The separate evolutions of biology and **psychology** have led to disadvantages in both approaches to the study of cognition. In the psychological tradition, the clearest problem has been the lack of evolutionary, comparative considerations and awareness of the natural context of cognition. On the other hand, the ethological tradition, particularly behavioural ecology, has focused heavily on functional and evolutionary questions with little consideration of the proximate mechanisms of cognition. However, in the 21st century, the study of animal cognition has become increasingly integrated between the two disciplines. While traditional boundaries remain, both biologists and psychologists have called for a 'synthetic approach', as evidenced by the many labels used to describe the field that studies animal cognition (i.e. comparative cognition, cognitive ecology, **evolutionary psychology** and **cognitive ethology**); to truly understand cognition, we need to follow **Tinbergen's four questions** framework and integrate questions

and answers about cognition from all levels (causation, ontogeny, function and evolution) into a coherent whole.

An evolutionary approach to cognition

An integrative understanding of cognition requires more than the sum of separate pieces and, as with all biological phenomena, behaviour and cognition cannot be fully understood without consideration of evolution. Although research focusing on proximate mechanisms is interesting in its own right, considerations of the function and evolution of cognition can inform and guide such work. From an evolutionary perspective, cognitive abilities are viewed as traits that are subject to natural selection; just as the beaks of Darwin's famous finches have evolved in shape and size in response to seed abundance and type, cognition has also evolved to solve ecological problems. This adaptive view of

P.112

cognition has led several researchers to argue that the mechanisms of cognition are likely to be specialized for different information-processing problems, much as sensory systems have become specialized to gather different types of information from the environment. The belief that cognition is 'adaptively specialized' predicts that 'we should expect to find a collection of specialized computational devices designed for special purposes rather than a single general-purpose, problem-solving mechanism' (Shettleworth, 1998, p. 42). In contrast to the general processes view described earlier, this paradigm views associative learning as one specific 'computational device' or 'module' for learning about causal relationships between events. Other modules may exist for solving different types of problems, such as learning spatial relationships or social ones. The exact nature of these proposed modules, their neurological underpinnings and how they may function to produce cognition are not yet clear. They pose some of the most critical and exciting questions for cognition research today.

Animal behaviour and cognition

Great animal behaviourists like **Niko Tinbergen**, **Konrad Lorenz** and **Karl von Frisch** were also great naturalists who recognized the fundamental importance of observing behaviour in an animal's natural environment. While laboratory-based studies of behaviour are necessary, behaviour in artificial settings is often very different from behaviour in nature. Thus, the logical place to begin studying behaviour is to identify and observe it in the field, as do naturalists. Given that cognition plays a critical role in many aspects of an animal's life and how it behaves, the study of cognition should likewise include field-based observations and studies.

This need is perhaps best illustrated by cognitive research investigating how animals perceive their environments. As articulated by Jacob Von Uexkull's concept of '**umwelt**', animals inhabit unique sensory worlds. To understand how different animals process sensory information, it is necessary first to know what type of sensory information is being collected and how it is being used; such information comes from observations of the animal in its natural environment. For example, the star-nosed mole possesses a unique 'star' appendage that sprouts from the end of its nose. Its function as a highly specialized touch organ was deduced from observations of moles using the appendage to detect, identify and eat prey with remarkable speed. Subsequent research on this extraordinary organ has uncovered striking similarities in the somatosensory system of the star-nosed mole and the mammalian visual system, and shed light on general principles of how the brain organizes sensory information.

The naturalist perspective of animal behaviour has proved to be vital in other areas of research in animal cognition. One area that illustrates this well and also demonstrates how biological and psychological approaches are being integrated is research on spatial cognition in food-storing birds and central-place foraging insects. Like the Clark's nutcrackers mentioned before, several species of birds - primarily parids (chickadees and titmice), corvids (jays, crows and nutcrackers) and sittids (nuthatches) - hide food in a large number of locations at summer's end, and then recover the food as needed throughout the winter

and spring. Using a combination of field observations and carefully controlled experiments in the laboratory, researchers have shown that many food-storing birds are using spatial memory to recall where they hid their seeds, with remarkable accuracy. The results suggest the possibility that the foraging ecology of food-storing birds has shaped specialized memory systems. If so, we might predict that certain species that rely more on food caches have a better-developed spatial memory.

One testing of this idea was a comparative study of the long-term spatial memory of four seed-caching corvids. Field observations of nutcrackers and pinyon jays show that they rely on cached seeds for a longer period of time than do Western scrub jays and Mexican jays, and thus would be predicted to have superior spatial abilities. In a laboratory setting, birds were allowed to cache and later given recovery sessions at varying time intervals. The results showed that there were differences in ability to locate hidden caches: nutcrackers and pinyon jays had better long-term spatial memory than the species that were less dependent on stored food, the Mexican and scrub jays. To test whether these results were specific to cache recovery tasks or were indicative of overall superior spatial memory abilities, comparisons of these species were also performed using different spatial tasks. Studies using radial mazes and operant tests, well-developed experimental paradigms in psychology, confirmed that the birds that relied more heavily on stored food, the nutcrackers and pinyon jays, performed better on spatial tasks than the species less reliant, the Mexican jays and scrub jays. Together, these studies provide strong evidence that spatial cognition in food-storing birds is shaped by its foraging ecology.

Foraging insects face different spatial challenges in nature from those of food-storing birds. For insects such as honeybees and ants that are central-place foragers, the task is to find their way to a goal, whether it is their nest or a good food source. Many such insects are known for their remarkable ability to accomplish this; honeybees, for example, will return repeatedly to a specific location of a rich nectar source several kilometres away. Much research in this area has focused on how animals learn and use landmarks and has used well-developed techniques from psychology, such as the radial-arm maze, to study spatial learning in the laboratory. These carefully controlled studies have revealed a great deal about how landmark information is encoded and used on a small scale.

However, studies of insects foraging in their natural environments have led to a richer understanding of spatial cognition. For example, field studies have revealed that *Catalgyphis* sp. ants use path integration to navigate in landmark-barren deserts, and honeybees use the sun as a directional compass. Using path integration and compass orientation probably involves a different set of computational problems and solutions than using landmark information does, and thus highlight the importance of studying spatial cognition in a variety of contexts. Moreover, extensive studies of honeybees and ants show that they use multiple strategies for navigation. In honeybees, for example, large-scale navigation involves the use of the sun as a compass and landscape features as landmark guides, while small-scale navigation near the goal involves the use of landmarks close to the goal, and odour cues. An integrative theory of spatial cognition requires an understanding of how various strategies are integrated to allow

P.113

animals to find their way around. This can best be accomplished by combining insights from the laboratory with studies in the field, and by integrating insights from both biological and psychological perspectives.

Research in spatial cognition is but one of many areas that are successfully integrating psychological and biological traditions and developing the integrated answers about behaviour advocated by Tinbergen. Other areas, such as communication, are discussed in other entries of this encyclopedia.

Cognitive bias

Cognitive bias describes the altered perception of positive and negative events resulting from an individual's background emotional state. In human psychology, studies on individuals experiencing particular **emotions**, which can be either reported (e.g. **depression**) or experimentally induced, report a change or bias in information processing. These cognitive biases can be grouped into three types: attentional bias, memory bias and judgement bias (see Paul *et al.*, 2005 for a review).

In the field of animal welfare science, cognitive bias can be considered a subjective component of emotion, or affective state, providing an additional approach to physiological and behavioural assessments of **welfare**. Although the observation of cognitive bias may indicate a component of emotional state, the accompanying conscious experience of emotion in animals cannot be assumed (Burman *et al.*, 2008) (**see: Consciousness; Sentience**). In cognitive bias tests on animals, the subjects are taught to respond to positive and negative reference stimuli, and then presented with intermediate (ambiguous) probes, their response to which is taken as an indicator of their cognitive bias.

For example, Burman *et al.* (2008) trained rats in a spatial discrimination task to recognize two reference locations (rewarded and unrewarded). Once the rats had successfully discriminated between the two reference locations, three ambiguous probes, one midway between the two reference probes and the other two between the midway probe and each of the reference locations, were presented to the rats. In this example, the average group latency of two groups of rats was compared; the group of rats that had been kept in an enriched environment (assumed to have a relatively positive background emotional state) had a longer latency to approach the near-negative probe, indicating a more optimistic-type bias when compared with the group of un-enriched rats (assumed to have a relatively negative background emotional state), which had a higher latency to approach this probe, indicating a more pessimistic-type bias.

Cognitive dysfunction

Advances in the management and care of **companion animals** mean that an increasing number achieve their lifespan potential, and so all conditions associated with old age are being seen more frequently by veterinarians. Ageing brings both specific and general changes in organ structure and function, which can lead to behaviour problems that are often of welfare concern. Ageing and cognitive dysfunction are not the same, and the latter is not an inevitable consequence of the former. Unlike many age-related problems that reflect compensatory behaviour for the inevitable challenges and changes associated with the ageing body, e.g. increased irritability associated with the **pain** of arthritic change, cognitive dysfunction is a condition with a specific pathology, which is being defined increasingly well. A range of otherwise unrelated medical conditions or environmental stressors in the older animal may unmask cognitive decline. This does not, however, mean they are the cause of the problem, which is related to the ageing **brain**.

The ageing process is associated with two key variables, which give rise to the collection of problems labelled as age-related disorders; first, the increase in time the animal has been alive raises the cumulative risk for the animal to be afflicted with a random, spontaneous or time-dependent event. This includes an increased risk of spontaneous lesions such as those due to ischaemic damage or certain types of neoplasia. Secondly, there are physiological changes associated with ageing, which not only affect cells but also their non-cellular constituents after they have been produced.

Theories of ageing concern the cumulative effect of random mutations or cross-linkages in DNA and the effects of cumulative damage from free radicals (including reactive oxygen species) on tissues. In addition, the possibility of an internal clock in the hypothalamus controlling the process through the endocrine system has also been speculated upon. As a result of ageing, brain mass decreases, ventricle size increases and the meninges thicken. Some selective loss of nerve cells occurs but, more importantly, there is a loss of neural connections and the development of plaques in those cells that remain. In some these take the form of neurofibrillary amyloid deposits and granulovacuolar degeneration, which is

P.114

associated with Alzheimer's disease in humans, which has analogues, known as cognitive dysfunction, a form of senile dementia in some domestic species, notably the dog and cat, which show some but not all of the changes seen in the early stages of human Alzheimer's disease.

Dementia has been defined as a 'global deterioration of intellectual and cognitive functions characterised by a defect of all five major mental functions: orientation, memory, intellect, judgement and affect, but with persistence of a clear consciousness' (Timiras, 1994). The acronym DISH A has been used clinically to describe the most common signs of cognitive decline associated with dysfunction in companion animal species: Disorientation; altered Interactions with people or other pets; Sleep-wake cycle alterations; House soiling; and altered Activity level (Landsberg *et al.*, 2003).

However, these categories do not describe all of the signs that might be associated with cognitive decline, with its increase in anxiety, decrease in hygiene/self-grooming, altered appetite, decreased responsiveness to stimuli, and deficits in learning and memory (especially discrimination and reversal learning and spatial memory) also being recognized. A decline in learning and memory can be demonstrated in dogs, beginning as young as 7 years of age, using a variety of neuropsychological tests. However, clinical cases of cognitive dysfunction syndrome are seldom identified until the age of 11 years or older. Data on cats are less consistent and not as scientifically robust. Both species may be useful models of different aspects of the pathology of the condition in humans.

Cognitive ethology

The term cognitive ethology was coined by Donald Griffin, an opponent of radical **behaviourism**, in an attempt to encourage scientists to investigate mental states, such as consciousness, in non-human animals. It is a branch of ethology concerned with the influence of conscious awareness and intention on the behaviour of the animal. The evolution and context of the behaviour is important in the study of cognitive ethology, and animals are usually observed under fairly natural conditions and with biologically relevant tasks or stimuli. Cognitive ethological studies also emphasize broad taxonomic comparisons instead of focusing on a few representatives from a few taxa. The overall goal of cognitive ethology is to understand the phylogenetic distribution of mental processes and their significance for the evolution, development, causation and adaptiveness of behaviour (see: **Tinbergen's four questions**).

Cognitive map

Cognitive maps are a type of mental processing or cognition used to structure and store spatial knowledge into an internal representation of the environment. These 'mental maps' of the spatial environment can help enhance recall and learning of information by allowing visualization of images in order to reduce cognitive load.

(LMD)

Cognitive model

Cognitive models are used for the comprehension and prediction of cognitive phenomena or processes. They usually focus on single cognitive phenomena or processes, on how two or more processes interact (e.g. decision making) or on how to make behavioural predictions for a specific task or tool.

(LMD)

Cold stress

Cold stress refers to a fall in the core body temperature below the thermoneutral zone, and can result in clinical hypothermia. Animals are generally quite tolerant of low temperatures, but cold stress is more likely when these are accompanied by strong winds or draughts or damp conditions, which affect the insulation properties of the coat or pelage. The provision of shelter is therefore important in preventing this problem in these conditions. Animals adapted to living in cold climates often use fat deposits to provide insulation not affected by these conditions. When temperatures drop, an increase in basal metabolic rate is necessary to maintain activity, but food may be limited at these times and so the animal may enter a state of torpor or hibernation to minimize energy demands.

Collar

Collars are bands of resilient, usually flexible, material placed around the neck or sometimes the head of animals to restrain and lead them, the premise being that where the head goes, the body will follow. They are used in dogs for restraint and leading, in cats to carry identity discs and in a variety of farm species for tethering. Apart from traditional 'flat collars' that work simply by applying pressure to one side of the neck, collars may be designed to constrict the neck. Examples include slip collars (that have a discrete section that can be tightened), choke chains (also known as check chains) and pinch collars or prong collars (with elements that protrude inwards when the collar is tightened).

Collars with prongs that face the dog's neck are controversial, since they can damage the soft tissues under the

P.115

skin of the neck. That said, any collar that constricts the dog's neck can be used abusively and injudiciously to the extent that many trainers avoid using them or advocating their use. Good trainers can

generally get the same or better results through heelwork (during which the dog walks close to the handler's leg), without the use of force.

The use of electric 'shock collars' is also highly controversial, especially in the hands of inexperienced pet owners or those seeking an alternative for consolidated shaping and positive **reinforcement** training. Their use has been outlawed in some countries. In contrast, 'head halters' or 'head collars' are popular among canine behaviour therapists since they are generally useful, especially in restraining and training large dogs or those that have undergone habituation to regular collar pressures. Pulling on the leash places pressure on the dog's muzzle and neck, via a ring under its jaw, and thus guides the head and consequently the body.

A further modification on the traditional collar is the 'spray collar', which emits an **aversive** but non-toxic atomized aliquot of fluid, such as a citronella-scented preparation. Some owners find bark-activated versions of these devices effective in controlling unwanted barking. The extent to which other unwelcome behaviours can be effectively eliminated by remote punishment mediated through such spray collars depends entirely on the operator's consistency and timing.

Modified collars may be used to prevent auto-grooming that is inappropriate (e.g. after surgery or in cases of self-mutilation); examples include so-called Elizabethan collars (in small animals) and neck cradles (in horses).

Because both **crib-biting** and **wind-sucking** are accompanied by characteristic flexion of the horse's neck, they can be discouraged by the application of a collar that punishes the flexion with discomfort. The typical (anti-)cribbing collar is a simple leather strap incorporating a galvanized, hinged arc that accommodates the trachea and allows normal breathing, even when tightened to the point where neck flexion and/or engulfing air into the oesophagus are not performed. It is possible that the presence of a constriction in this site not only makes crib-biting uncomfortable but may also make the behaviour less easy to consummate, since the terminal grunting in this oral-based stereotypy is known to involve distension of the cranial oesophagus. Modifications of the collar include the use of leather or metal spikes to heighten the discomfort associated with neck flexion, as well as designs made entirely of leather and often marketed as being distinctly 'humane' (even though they work along the same principles as above). Horses often adapt to the constriction of the collars, which are subsequently tightened, occasionally to the extent that skin trauma follows. Combinations of straps that can be tightened around different parts of the cranial neck have been advocated to reduce tissue damage at the poll.

Commercially available electronic training collars can be programmed to discharge when the neck is flexed or remotely controlled, so that the horse does not associate punishment with the presence of a human. The use of dummy collars before aversion therapy of this sort may avoid the horse associating punishment with the collar itself. It is reported that by applying an electric shock after the horse has been grasped, but before it has engulfed air, punishment and extinction of grasping may be achieved. However, follow-up studies in 60 cases of aversion therapy using electric shock collars indicated that only nine 'cures' were effected and, of these, three required further shocks after 9 months (Owen, 1982). One practical problem with such aversive techniques may be that the horse may not crib-bite for a long time after the first shock, so constant observation and considerable patience may be required for the trainer to maintain the contingency between crib-biting and punishment. A more profound ethical problem is that physical prevention or punishment may increase distress levels. It is possible that elimination of one stereotypic behaviour may precipitate unwelcome behavioural side effects, including the emergence of a modified or alternative stereotypy.

Colostrum

Colostrum is the first fluid produced by the mammary glands for the initial few days following parturition. It is somewhat different from the milk of the main lactation, being high in carbohydrates, proteins, vitamins and minerals, and also containing antibodies that help to protect the offspring from diseases early in life. Animals that do not receive colostrum tend to be sickly and have an increased mortality rate.

Comfort behaviour

Comfort behaviour is a generic term given to a heterogeneous group of activities thought to be involved in body maintenance, which includes keeping clean and relieving skin irritation and muscle tension. For example, cattle swish their tails and stamp their legs to keep flies on the move; during dust bathing, chickens lower themselves into a sitting position, fluff their feathers and move their wings such that dust (or other material) moves through the wings and on to the back; pairs of horses stand nose to tail so that both animals benefit from the tail movements of the other; ducks dip their heads repeatedly in water as part of bathing; pigs can scratch the head and neck region by lifting a hind leg or scratch their hindquarters by sitting down and moving backwards and forwards.

Indeed, a variety of comfort behaviours have been described for birds, rabbits, pigs, cattle and other animals, including: wing flapping, feather raising, stretching (wing and leg), scratching, shaking (head and body), preening, beak wiping, yawning, sneezing, tail wagging, tail flicking, hoof stamping, dust bathing, water bathing, **grooming**, rubbing, ruffling, ground scratching and wriggling. Other terms for comfort behaviour include comfort movements and comfort activities. Some of these behaviours involve interaction with environmental resources (e.g. dust bathing), while other behaviours are self-directed (e.g. **preening**).

A variety of factors affect the performance of comfort behaviours, including spatial limitations, social factors and

P.116

environmental stimuli. In some intensive housing systems space is restricted, and this may prevent the performance of comfort behaviours. For example, as cage height increases, hens are more likely to engage in head stretching, head scratching and body shaking. Similarly, when given increased cage area, hens are more likely to engage in head scratching, body shaking and feather raising (Nicol, 1987). These findings indicate that hens require adequate space in order to perform specific comfort behaviours.

In addition to spatial limitations, the presence or proximity of other animals may influence the performance of comfort behaviours. For example, the frequency of tail wagging, body shaking and preening increases when other hens are visible or in close proximity, while the frequency of other comfort behaviours, such as beak wiping, are not affected by visible contact with **conspecifics** (Nicol, 1989).

Social grooming is another example of how performance of comfort behaviours can be influenced by the presence of other animals. For instance, when horses perform **allogrooming**, animals face one another and use their lips and teeth to groom the neck, withers and back of the other animal.

The performance of some comfort behaviours is closely linked to the availability of environmental stimuli or resources. For example, functional dust bathing requires a loose substrate for chickens to spread over their body and through their wings. In addition, comfort behaviours are often thought to relieve irritation from environmental factors such as parasites or weather. For example, male shelducks perform nearly twice as many body shakes in response to rain, compared with visual contact with another displaying male or no other stimuli (Sebbel *et al.*, 1998).

Examining the factors that affect the performance of comfort behaviours highlights the heterogeneity of this group of activities. Although it may be convenient to group behaviours such as yawning, preening and wing flapping into the same category, the function of these behaviours may differ. For example, preening is likely to be involved in feather maintenance, but birds may also preen during an aggressive social interaction (**displacement behaviour**). Similarly, wing flapping may be important to relieve muscle tension, but cocks may also flap their wings to communicate to other males (see also: **Communication**). Finally, yawning is thought to be important for forceful exchange of gases in the lungs, but it is also socially facilitated, indicating that it may have other functions.

Knowledge about the specific function of these activities is important when using comfort behaviour to assess animal welfare. Indeed, multiple functions for a single behaviour can complicate the interpretation of comfort behaviours when they are used as measures of animal **welfare**. In addition, there are other difficulties interpreting the importance of comfort behaviours when assessing animal welfare (see: **Welfare measurement**). For example, in the spatial limitation example described above, an increase in the frequency and the ability to perform comfort behaviours in larger cages is interpreted as good for the hens. However, an increase in the frequency of comfort behaviours may not always be a positive welfare indicator. For example, there may be clear differences in the frequency of comfort behaviours between animals housed in a parasite-ridden aviary compared with those housed in one well maintained. Hens may perform more scratching and preening in the parasite-ridden aviary, although this does not indicate that their welfare is better in this system. Like many other measures of welfare, comfort behaviours need to be interpreted in conjunction with other measures, such as parasite load.

Learning about the motivation to perform comfort behaviours is an area that has the potential for improving our understanding of the importance of these behaviours for animal welfare. The motivation to perform comfort behaviours can be assessed in a number of ways. Environmental costs, such as restricted **time budgets** or limited space, may be used to assess the importance of various comfort behaviours, particularly for self-directed comfort behaviours. In contrast, the importance of comfort behaviours that involve environmental resources can be assessed by manipulating the availability of these resources (see also: **Behavioural need**). Finally, motivation to perform comfort behaviours can also be assessed by depriving animals of the possibility to perform these behaviours and monitoring '**rebound**' behaviour. The physical benefits (e.g. feather condition, bone strength) of comfort behaviour can also be determined by preventing animals from performing them and assessing changes in condition. As with motivation, documenting the health benefits of comfort behaviours improves our understanding of the importance of these behaviours for animal welfare.

In addition to the group of comfort behaviours describe above, the term 'comfort' is used in other contexts, such as in relation to thermoregulatory behaviour (see: **Thermo-regulation**) and differences in time budgets, e.g. **resting behaviour** in cattle.

Commensalism

Commensalism is a symbiotic relationship between two or more organisms from different species in which one organism benefits from the relationship while the other is unaffected by it. Commensal relations may form between and within plants, fungi and animals, although some argue that no relationship is completely neutral, and that therefore the relationship may be either mutual or parasitic.

(LMD)

Communication

Communication is the transfer of information from a sender to a receiver, where both the sender and the receiver map a signal to a particular meaning (see Hauser, 1996, for several other definitions). Although some may consider information transfer as anything that reduces the receiver's uncertainty about future events, such a definition implies that communication is a one-way system and does not take into account manipulation, or even the intentional ploy of the sender, in some cases to enhance the receiver's uncertainty about future events. If the 'signal-to-meaning' mapping involves syntax (a formal

P.117

structuring of the signals in relation to each other), this is termed **language**.

Signal-to-meaning mapping does not necessarily involve intention or conscious processing. Plants have also been found to communicate information with each other; for example, undamaged sugar maple seedlings and maize synthesize compounds that make them less palatable - or even slightly toxic - when damaged, conspecifics emit airborne signals when their leaves are damaged and chemical signals can even be emitted that attract predators of the likely perpetrators.

Signals may be distinguished from cues in that signals can be varied behaviourally by the sender (for example, an animal can call or not call, as well as possibly use many varieties of a call), and involve some cost for the signaller to produce. In contrast, cues are typically always present, such as the warning or 'aposomatic' coloration of some poisonous species, and there are no extra costs associated with each usage.

In the animal kingdom every possible sensory information channel is exploited for communication. Sound waves are used, for example in song, grunts and calls, such as: (i) the low-frequency calls made by elephants, which travel through the ground and can be picked up by other elephants via their trunks and feet; (ii) the visual signals that are used in the form of colours and decoration, body language, gestures, facial expressions, light signals, dance, display and even the way in which a nest is built and decorated, as by the hammerkop (*Scopus umbretta*) to signal fitness to potential mates; (iii) chemical signals (see:

Chemical communication), including **pheromones**, which play a role in partner selection, signalling alarm and the setting out of trails, aversive defensive chemicals, chemical territorial markings and social odours, such as the chemicals exchanged between lions (and domestic cats) when rubbing their heads against each other, enhancing bonding; (iv) the vibration used, for example, by the southern green stinkbug (*Nezara viridula*) to signal both gender and location through the vibration of leaves attached to plants or trees; (v) the electricity used by some aquatic species, for example, the frequency of the electric discharge of the whale-faced marcusenius (*Brienomyrus brachyistius*) is used by conspecifics to determine gender (**see: Electric fields**); and (vi) touch, for example, the licking used as a greeting by marmosets (*Callithrix jacchus*).

The specific channel used for communication depends on the signal content, sensory ability of the species concerned as well as the prevailing environment for communication; for example, pigs often use auditory signals to communicate rapidly socially, as their natural woodland habitat is a barrier to visual signals.

Communication is generally focused on the needs of the sender or the receiver, linked to the survival of the individual or the species: to find a mate, to defend, to threaten, to mark territory, to coordinate **hunting**, to determine or establish a social hierarchy, to know something about the state of the sender (e.g. whether prepared to mate), etc. The needs of the sender and receiver in an evolutionary context do not require that communication is always truthful: senders can benefit by using signals to mislead receivers. For example, roosters will sometimes peck at the ground, as if foraging, even when no food is present, in an apparent attempt to attract hens to their vicinity. 'Honest' signalling is more likely if the signals are expensive to produce. For example, crowing acts as an honest signal of social status, in part because subordinates are more likely to be pecked by flock-mates if they crow.

Communication is not limited to social animals, although communication among animals living in groups tends to be more varied (both in channel use and the repertoires employed) compared with those living solitary lives. For example, bonobos (*Pan paniscus*) use facial expressions, gestures, calls, grunts, touch, grooming and even sex in communication (de Waal and Lanting, 1997), while the solitary living giant kangaroo rat (*Dipodomys ingens*) communicates mostly by leaving scent trails in the sand and by foot drumming (Murdock and Randall, 2001).

The total repertoire of signal-to-meaning mappings is vast for human beings (the adult 'mental lexicon' contains 50,000-100,000 words, depending on the level of education) compared with the signal repertoires available to other animals. For example, vervet monkeys living in Amboseli National Park in Kenya have three different alarm calls to signal danger: (i) leopard alarm calls enticing vervets to run into the trees; (ii) eagle alarm calls causing vervets to look up; and (iii) snake alarm calls making vervets look down (Seyfarth *et al.*, 1980).

Attempts have been made artificially to increase the total set of signals that are naturally available to chimpanzees (Rumbaugh *et al.*, 2003; Hillix and Rumbaugh, 2004), dolphins (Herman *et al.*, 1984), parrots (Pepperberg, 2000) and dogs (Kaminski *et al.*, 2004; Rossi and Ades, 2008). For example, a border collie named Rico, who knew the names for at least 200 objects (as tested by retrieving these objects), was taught almost 40 names for new objects in single trials, and was shown to remember these new names after a period of 4 weeks, making his performance 'comparable to the performance of three-year-old toddlers' (Kaminski *et al.*, 2004).

Although the human-like ability of 'fast mapping' was claimed for the process of name acquisition by Rico, methodological problems in this and other animal studies have not refuted the suggestion that the size, structure, use and acquisition of the mental lexicon in humans is qualitatively different compared with other animals. The human mental lexicon encodes, among other things, complex relations (e.g. 'later' and 'conclusion'), abstract categories (e.g. 'planets' and 'recursive') and syntactic features (e.g. 'gender' and 'number'). With the (spontaneous) intention to convey a message, humans normally produce

two to three words per second without repeating the same item and while making only one to two mistakes per 1000 words.

Humans learn signal to meaning mappings by using a **theory of mind** to understand word reference (e.g. to understand pointing, or to understand what the signaller attends to); humans do not have to be taught which items should be learned from among the total available input (e.g. 'this is not a car' does not contain a reference to a name ('not-a-car') as an entity), and humans learn words without reinforcement (Bloom, 2004; Markman and Abelev, 2004). Although research continues to investigate to what extent these and other features are part of the signal to meaning mapping in other species, it is quite unlikely that all the features found in humans will be found in any single other species, due to differences in the evolutionary histories of humans and non-humans, including our closest primate cousins.

P.118

Most signals have evolved for communication between members of the same species, but some signals are also used for interspecific communication. For example, prey species use a variety of signals in response to the presence of potential predators, such as 'alarm calls' by chipmunks or 'stotting' by gazelles (**see: Alarm reaction**). These signals may have evolved as a way of warning group mates, but they also function to inform predators that their presence is known and that the probability of success is therefore low. By attending to such signals the predator saves the costs associated with (unsuccessful) pursuit.

It is generally accepted that signals have evolved by natural selection out of behaviours that had non-signal functions (Hauser, 1996); for example, urinating has in some species developed into a signal for territory marking. Although historically emphasis has been given to the role of selection operating mostly on the sender to convey unambiguous information for the recipient, during competitive interactions selection also operates 'against individuals using displays that are highly predictive of their subsequent behaviour' (Hauser, 1996). While it is in the interest of the sender to deceive and to manipulate the truthfulness of a signal, it is in the interest of the receiver to decode a signal reliably, and to resist any manipulation successfully. In studying the evolution of communication, and in comparing the signal to meaning mappings between different species, it is important to focus on both senders and receivers and on both truthful and deceitful aspects of communication (**see: Deceit behaviour; Honest signals**).

For people working with animals, an understanding of their signals is especially important and, arguably, many of the animals that we have domesticated have become proficient at recognizing the signals we use (**see: Dog**). Although there appear to be some common properties to certain signals (for example, short, high-pitched rising tones tend to be used to communicate the need to speed up across taxa, and longer, low, descending tones tend to be used to inhibit behaviour), similar signals may also be used quite differently between taxa: for example, the baring of teeth by a human may represent a friendly smile, but a similar gesture by a dog can have a defensive/aggressive meaning. A failure to appreciate this is believed to be one factor contributing to the higher rate of dog bite injuries in children (**see also: Bite prevention programmes**).

Communitarianism

Communitarianism is an approach to ethical and social issues according to which elements of community (friendship, common purpose, tradition) possess intrinsic value and justify the imposition of rules and moral norms. This contrasts with theories according to which community matters only indirectly - for

example, because it makes people well off (utilitarianism) or would be agreed to by reasonable people (contractarianism). The debate about communitarianism may be relevant to discussions on traditional forms of animal use.

(PS)

Companion animal

Usually preferred in the scientific literature to 'pet', this term usually refers to any animal kept primarily for companionship. It is therefore a functional definition, and strictly speaking could be applied to almost any non-human species. Companion animals may therefore belong to any of the groupings used by veterinarians (farm, small, equine and exotic), even though the companion animals that have received most research attention from ethologists (dogs and cats) fall into the 'small' category. However, being a member of one of these species does not automatically confer companion animal status; consider, for example feral cats, or dogs bred primarily for their meat or fur. The term 'companion animal' should therefore be applied to individual animals, not a breed or species. The current preference for 'companion animal' over 'pet' appears to stem from a desire to indicate that such animals have a status of their own, and are not simply the possessions of their owners.

Some authors restrict the use of 'companion animal' or 'pet' to domesticated species. However, this would technically exclude animals that were originally wild-caught and have been tamed (parrots, for example) and then develop a close relationship with an owner for many years. Moreover, it glosses over the differences in the extent of domestication that exist between and within the species traditionally regarded as 'companion'. For example, pedigree Persian cats fit the

P.119

definition of domestication in that their breeding and nutrition are completely controlled by man but, strictly speaking, non-pedigree cats might not, because they generally select their own mates (from any cats nearby that have avoided neutering).

It has been suggested that companion animals should encompass all those shown special kindness and consideration by people, but this would include most wild animals in zoos, and also wild birds deliberately fed in gardens, neither of which would normally be thought of as being pets. The requirement for the animals to be under human control and kept primarily for companionship therefore seems to be essential. The definition is therefore focused on the owner's perception of the relationship; whether the animal perceives the owner as a 'companion' (member of the same affiliative social group) is a separate issue.

However, the assumption is usually made that in a successful companion animal-owner relationship, social benefits accrue to the animal as well as by the human partner. This is most obvious in dogs and also cats, which display species-typical affiliative behaviour towards familiar people. It is less apparent in some other animals that can be referred to as 'pets' - for example, fish in tanks (fish are probably the most numerous pets, in terms of total numbers of individuals). It is still less certain how to classify insects such as exotic spiders, or the crickets and beetles kept by children in Japan and referred to as 'mushi'.

Because 'companion animal' describes current status, it need not apply to an animal throughout its life. For example, working dogs, initially kept mainly for utilitarian purposes, may be 'retired' to their former keeper or elsewhere and thereby become companions. Logically speaking, a dog that is abandoned by one household and spends time at an animal shelter prior to being adopted by another should temporarily lose its 'companion' status, but this is probably one distinction too far. More problematic are animals that simultaneously fulfil companion and utilitarian roles. Examples of these are widespread both geographically and across species. Many of those who use dogs for guiding and searching functions form a strong emotional bond with them. Indian **elephants**, an undomesticated species that is easy to tame, are regarded as companions as well as working partners by their mahouts. Finally, many people would automatically exclude animals that are eventually destined to be eaten, even though some undoubtedly

provide companionship for their owners; such relationships occur in a wide range of cultures, from the New Guinea village where pet pigs are slaughtered for ritual purposes to the modern hobby-breeder of rare types of domestic stock that are, for example, given names but are ultimately destined for the table.

Overall, it appears to be easy to classify some animals as companions - the family dog for example - but more difficult to define the boundaries of what should be excluded. This appears to reflect a continuum from those animals that are exclusively kept for companionship for their whole lives to those for which companionship is only a minor or temporary part of their relationship with man, and in which other, such as utilitarian or decorative, functions are predominant. Although it is incorrect to define a companion animal according to which species it is, it is self-evident that some species occupy such a role much more than others do, and also that there are qualitative differences between species in the type and extent of companionship experienced by their owners: otherwise, all species would be interchangeable. Some authors have wished to refine the definition of companion animal in order to address such questions as 'why do people keep pets?' or 'what benefits do people get from pet-keeping?' more effectively (**see: Anthrozoology**). Others have pointed out that, due to the differences between the species involved, such questions may be oversimplified, and recent research has indeed suggested that cat ownership and dog ownership (for example) may differ from one another both in motivation and effects.

Comparative biology

Comparative biology concerns the study of homologous (**see: Homology**) and analogous (**analogy**) features in living systems and their relationship to each other. Comparative biology can extend into any of the life science disciplines from the molecular to the organismal or environmental, such as genetics, anatomy, psychology (**see: Comparative psychology**) and **ecology**. In some cases where the focus of the comparison is on the phylogenetic relationships between individuals, the discipline may be prefaced with the term 'evolutionary', as in evolutionary psychology.

(DSM)

See also: Comparative method

Comparative method

The comparative method is a cross-species comparison that relates species differences in behaviour, anatomy or physiology to differences in species ecology. For example, variation in testicular size is closely associated with mating system in primates, bats, antelope, birds, amphibians, fish and insects. Essentially, males have relatively large testes in species whose mating system is characterized by female promiscuity - an adaptive response to the risk of sperm competition. In using the comparative method it is important to control for both confounding variables (especially body size) and the non-independence of species data. Because species within a genus tend to have similar characteristics due to shared common ancestry, analysis of species data reflects phylogeny rather than ecology. Thus, modern comparative

methods attempt to distinguish independent evolutionary origins of character states from cases of identity by common descent.

Comparative psychology

Comparative psychology is the study of the development and evolution of behaviour across species. Modern-day comparative psychologists study a wide range of animal behaviours. However, early comparative psychologists focused specifically on animal **cognition** and **intelligence**, basing their research on the belief that the origins of the human mind could be

P.120

understood by studying the animal mind. **Charles Darwin** (1809-1882) is credited with being the father of modern comparative psychology because his theory of **evolution**, which revolutionized biological science, stimulated scientific exploration of the mental life of animals.

In his *On the Origin of Species*, Darwin suggested that natural selection occurred through biological principles. Darwin stated that the mental life and behaviour of organisms followed a continuum such that there were no qualitative differences in behaviour and mental functioning. In support of his idea of mental continuity between humans and animals, Darwin described: the cleverness of animals in making use of their natural environment (e.g. dam building in beavers); the adaptability of domestic or captive animals to unnatural environments, which he took as evidence of reasoning; their propensity to imitate humans or other animals, implying rational inference; their intercommunication of ideas and plans of action, suggesting cooperation; and their similar emotional reactions, suggesting that animals are capable of deceit, shame, a sense of justice and **altruism**. He did, however, concede that there may be quantitative differences across species such that animals could be divided between those that were capable of higher-level thought processes and those that were capable of only precursors for higher-level thought processes.

By stressing the continuity of species, Darwin made the study of animal behaviour crucial to the understanding of human behaviour. Although much of Darwin's theory of the continuity of mental functioning in humans and animals was based on anecdotal evidence, his theory of evolution served to generate a number of testable hypotheses and inspire new methods of scientific enquiry, which allowed scientists actively to pursue the collection of evidence for mind or intelligence in animals.

The focus of experimental research in comparative psychology following Darwin's theory of evolution took one of two approaches. Scientists either sought evidence to suggest that humans and animals were alike in mental functioning or that humans were fundamentally different from animals in mental functioning. One of the first scientists formally to study animal intelligence was **George John Romanes** (1848-1894). Romanes was directly influenced by Darwin's readings and sought to demonstrate the similarity between human and animal functioning by studying a wide spectrum of species, ranging in physical size and complexity from single-celled organisms to vertebrates. Romanes provided anecdotal evidence for animal reasoning and intelligence from watching the behaviour of animals in their natural environment.

Other researchers criticized his use of subjective evidence and sought to provide a more objective and experimental methodology for studying animal behaviour. For example, the theories of classical

conditioning developed by **Ivan Pavlov** and **instrumental conditioning** developed by E.L. Thorndike together explained objectively a great deal of behaviour and seemingly cognitive behaviour observed in both humans and animals, strengthening the idea that humans and animals were not dissimilar in their learning abilities.

These two theories served as catalysts for the development of a new movement in psychology known as **behaviourism**, which dominated the field of psychology for several decades. Progenitors of this movement sought to remove all mentalistic terminology such as **consciousness**, mind, imagery and mental states from the interpretation of both animal and human behaviour. They believed, unlike Darwin, that the behaviour of organisms differed not in terms of the quality of responses to stimuli but in terms of quantity. That is, more complex organisms might be capable of emitting a greater variety of responses to a greater variety of stimuli, but the principles underlying those responses are no different to those governing the behaviour of less complex organisms. The widespread acceptance of the universality of behavioural and cognitive mechanisms led to a bias in searching for generalities in behaviour that still exists to some extent today.

In contrast to studies underscoring the generality of behaviour across species, some studies began to show that species may, in fact, differ both qualitatively and quantitatively in their abilities to perform similar tasks. Researchers studying the biological bases of animal behaviour in fields such as **ethology**, **behavioural ecology** and **sociobiology** criticized comparative psychologists for a number of factors, including focusing their research on behaviour observed in laboratory settings rather than in the field, studying a limited number of species and concerning themselves mostly with learning at the expense of ecologically relevant behaviour.

These fields caused comparative psychology to take a more evolutionary approach to their study of animal behaviour. It was argued that, for comparative psychology to survive and compete in the intellectual arena with ethology, behavioural ecology and sociobiology, it had to become more integrated with these fields by choosing species based on their phylogenetic origins rather than on convenience, by increasing fieldwork or research in semi-naturalistic settings, by adopting a more ecological approach and by incorporating the theory of evolution into the **anthropocentric** approach in their study of animal behaviour.

Comparative psychologists are now beginning to promote an ecological approach, as opposed to a strictly generalist approach, to learning and cognition. It has long been accepted by scientists that environmental pressures could create specializations in sensory, motor or physiological processes in animals through the process of natural selection. It is, therefore, not unreasonable to think that the same environmental pressures could create specializations in memory and brain function. The ecological approach takes into account the natural history of the organism by identifying and designing experiments to test learning abilities that may be important to the organism in nature, and determining how and why these capabilities may have evolved.

Thus the current field of comparative psychology seems positioned to bridge the gap between psychologists and ethologists by attempting to discover not only similarities, but also differences, both within and across species, based on their phylogeny and evolutionary niche. Modern comparative psychologists are interested in a wide range of behaviours, including orientation and locomotion, feeding and foraging behaviour, predator defence and prey-predator interactions, reproduction, **social behaviour** and **social cognition**, **communication** and **language**, learning, animal cognition or intelligence and **theory of mind**. They study animal behaviour in both the laboratory and the field, in basic and applied settings, using a variety of methodologies.

P.121

Comparative research on species differences in learning and memory has increased dramatically and is gaining in popularity in the scientific literature, and is important for those interested in applied animal

behaviour and welfare. Understanding the similarities as well as the differences between species can be valuable for improving the management of animals in captivity, specifically in terms of feeding, providing social opportunities and designing enrichment that stimulates the animal mind in a manner that is appropriate for each individual and species. Knowledge of the foraging skills and learning capabilities of a species could also be helpful in designing reintroduction programmes. Finally, research from the field of comparative psychology provides insight into the intelligence of animals, which can be valuable for influencing public opinion and increasing the favourability and appreciation of a species.

Compulsive disorder

A compulsive disorder describes a repetitive or sustained behaviour that does not change much from one situation to another and which is not a normal part of the ethogram of the organism within the given context. Historically, within the animal science literature the terms compulsive behaviour/disorder (or obsessive-compulsive behaviour/disorder) have been used synonymously with the term stereotypy, although the two are clearly distinguished in the human literature. A compulsive behaviour is highly motivated towards achieving a specific goal and, while it can become ritualized and quite rigid in its execution, the behaviour remains goal-focused, while the term stereotypy refers to motor acts that are uncontrollably released and have no obvious goal. The importance of this distinction is increasingly becoming recognized in the clinical animal literature, as it may ultimately be of prognostic and treatment value.

Some compulsive behaviours, such as acral licking of the carpus in the dog, have been proposed as models of human obsessive-compulsive behaviour, and respond to similar treatments (serotonergic agents). However, the 'obsessive' dimension cannot be determined in non-human animals and, in humans, the obsession does not necessarily correlate with the compulsion and so this element of the terminology has been rejected by many. Compulsion can be determined by the high motivation to perform the behaviour even in the presence of physical and psychological barriers. Some stereotypic behaviours may be compulsive behaviours, e.g. weaving in the horse, but some compulsive behaviours do not fit the

definition of stereotypic behaviour as they are not repetitive, e.g. light fixations in Border collie dogs, hence the preference for the term compulsion in the clinical literature.

Concentrate feeding

Concentrated feeds, or concentrates, are usually based on cereals or other high-energy and protein feeds. They are generally made into a pellet, or compound, with the addition of a binding agent, most often sugarcane molasses. Concentrates are fed to pigs, poultry and horses, and to cattle in situations where high performance is required or forages are in short supply. The allocation of concentrates should take account of the animals' physiological state, lactating or non-lactating, pregnant or non-pregnant, etc. The majority of dairy farmers prefer to feed concentrates to those cows giving the most milk.

The risk of upsetting the digestion of animals that have evolved to eat large quantities of herbage, by feeding high-concentrate diets and causing problems such as low milk fat concentrations or acidosis, has led to several developments in concentrate feeding. First, if high levels of concentrate are fed, it is better if they are based on digestible fibre, such as that from beets, rather than starch from cereals. The starch in compound pellets is exposed to rapid degradation by gastrointestinal bacteria. In some cases fats may be preferable to starch-based rations, but in ruminants they are likely to need protection from rumen degradation. Secondly, the concentrates may be fed at a low level several times during the day, rather than just once or twice a day, e.g. when visiting the milking parlour. This will help both to reduce excessive bouts of acid production by bacteria that reduce the efficiency of digestive function and also, in the case of cattle, to improve the efficiency of ammonia capture by ensuring a more even degradation of the concentrate feed over time. The high cost of producing, delivering and feeding concentrates compared with forages ensures that they are used in limited quantities, but they are an essential part of the diet of high-producing or potentially undernourished livestock that cannot meet their energy demands from the available vegetation alone.

(CJCP)

Concept formation

In 2002, Zentall *et al.* observed that 'there is, perhaps, no larger or more diverse literature within experimental psychology than that focused on categorization and concept learning'. Why, one may wonder, has so much scientific effort been invested in understanding how animals form categories and/or concepts. Why does it matter?

The fact is that animals often respond adaptively to objects or events they have never encountered before: a monkey meeting a strange, larger male will initially avoid it; a chicken moved to a new cage knows to drink from the new drinker and feed from the new feeder; and a pigeon in a Skinner box will peck at a new picture of a tree rather than at anything else if it had previously been rewarded for pecking at tree pictures.

P.122

Such appropriate and adaptive behaviours are expressions of an ability to categorize stimuli. When an animal responds adaptively to a new **stimulus** it is often because the new stimulus resembles others for which the appropriate response is already known: the monkey will have had previous encounters with larger males from which he has learned that larger males are likely to be aggressive, stronger and best avoided; the chicken will have had a drinker and feeder in its previous cage; and the pigeon will have learned to associate tree pictures rather than non-tree pictures with a food reward.

Generalizations across stimuli would be impossible without this ability to categorize. The animal would perceive every object or event as new and unique, and would have to respond to it as such. There is, therefore, clearly an advantage to be gained from being able to generalize across objects and events that are similar to each other, and from being able to sort them into categories on the basis of their resemblance. The crucial question with respect to concept formation is: which aspects of the stimuli do animals use to assess stimulus resemblance, i.e. category membership?

Adult humans often categorize objects and events with reference to abstract 'concepts'. The *Concise Oxford English Dictionary* defines a concept as an idea of a class of objects. However, in the terminology of this article, 'concepts' refer not just to classes of objects but also to classes of events and groups of any stimuli in general. Whichever stimuli (e.g. events, people, objects) we may refer to, the point is that, with concepts, category membership is on the basis of the abstract idea for which all members stand. The idea is 'abstract' in the sense that it is not necessarily dependent on any specific, concrete, physical features of the category members. Having the concept of 'growing', for example, is not based on what 'growing' things taste, smell, sound, feel or look like. Instead, it is knowing that all members of this category are increasing (in size, height, amount, degree and so on); examples would be a seedling tree, an infant or the human population.

Understanding whether and how animals form concepts is important because, if we care for animals and are concerned whether they are faring well under our care, we need to know how and to what extent they understand their environment; this includes whether they can, in fact, recognize an unfamiliar drinker as a new example of something similar learned in the past - and kind handlers as the ones in the blue overalls, and whether and how they recognize kin or discriminate between familiar and unfamiliar conspecifics (**see also: Kin selection**). Secondly, it may be important to know when, why and how the ability to form abstract concepts has arisen in the animal kingdom, and whether abstract concept formation is uniquely human or dependent on having **language**. A thorough review of all the theoretical and experimental work on the subject is clearly beyond the scope of this article. Instead, it aims to introduce the main relevant research approaches and, in doing so, draws on several thorough, but usually conflicting, reviews.

Much of our knowledge about category and concept formation in animals comes from laboratory studies with pigeons. Herrnstein and colleagues (1976), for example, investigated whether pigeons could learn to discriminate between images containing and not containing trees. In each training session, the pigeons were shown 80 different photographs, one at a time; 40 ± 5 of them were of scenes featuring trees ('tree-photos'). Note that the trees were of any type or description, and not necessarily the centre of attention in the pictures. 'Non-tree photos' were comparable to 'tree-photos' in every respect except the lack of a tree or part of a tree. Some images were presented more than once, some only once. If the pigeons pecked at the response key when a tree-photo was shown, they received a food reward; if they pecked for a non-tree photo, they received no food but a 10 s penalty delay before the next picture was presented. Over 120-131 such sessions, pigeons learned to discriminate between the two categories of photo: they pecked significantly more for tree-photos than for non-tree photos, and this discrimination applied even to pictures they had not seen before. Results such as these have been confirmed by many studies in different laboratories using different stimuli. Taken together, they show that pigeons can discriminate

between different stimuli (photos in Herrnstein *et al.*'s case) on the basis of which category they belonged to ('tree' or 'non-tree').

Subsequent studies have demonstrated experimentally that many other vertebrate species ranging from chinchillas to carp are also capable of category formation, on the basis of the presence or absence of certain physical features. Not all of these studies have used visual stimuli. Johnston and Jernigan (1994), for example, showed that male hamsters can discriminate between familiar and unfamiliar females on the basis of their scent; carp, a fish species with particular sound sensitivity, can be trained to discriminate between blues and classical music (Chase, 2001).

The now standard experimental method in such categorization tasks is to train animals with a 'training set' of repeated exemplars (examples) of the two categories, then to test whether they can transfer any learned discrimination to novel exemplars. In Chase's study, for example, the carp were first trained with a training set of John Lee Hooker (guitar and vocals) and Bach (oboe concertos) exemplars by rewarding a button press with food when John Lee Hooker was playing, but not when Bach was. The carp were then tested for transfer with a variety of previously unheard recordings of blues and classical music (baroque and other) from several other artists and ensembles.

Animals may also form categories when the respective stimuli do not share physical features but lead to the same outcome, response or reaction. Consider the results of a study with chimpanzees by Savage-Rumbaugh *et al.* (1980). The chimpanzees were trained to sort a mixed bin (training set) of three food and three tool objects (stimuli) into two separate bins. In tests they were then presented with a mix of new food and tool items, and the chimpanzees sorted them as expected into 'food' and 'tools'. Food items in the tests clearly differed physically from each other and from the food items used in the training sets, but they had something else in common: they all made the chimps salivate (Pearce, 2007). The animals may thus have learned that anything that makes them salivate belongs to one category ('food'), while any stimulus that does not belongs to the other ('tool').

Such experimental evidence has since shown that animals can learn to group primary stimuli together using secondary stimuli, even when the former are completely arbitrary and unrelated (e.g. chairs and cars). Pigeons, for example, might be trained to lever-press when they are shown pictures of chairs

P.123

and cars. When one of the stimuli (e.g. 'chair') is subsequently paired with a new response (e.g. button press), pigeons will tend to button-press also for the other stimulus (in this example, 'car'). This suggests that they had learned to treat chair and car pictures as members of the same category on the basis of their originally shared secondary stimulus (the lever-press) (see Urcuioli, 1990, for details of an elegant, if rather more complex, related experimental design). Such secondary stimulus generalization is, somewhat unhelpfully, also called 'mediated generalization', 'acquired stimulus equivalence', 'functional concept learning' or 'associative concept learning'.

Authors such as Thomas Zentall and Peter Urcuioli, who do refer to secondary stimulus generalization as associative concept learning, suggest it as one of several types of category formation by 'conceptualization' or, as Zentall and his colleagues put it, as one of 'three broad types of relations that appear to unite events into a category' (e.g. Urcuioli, 2001; Zentall *et al.*, 2002). In Zentall's terminology, the other two types of concept are 'perceptual' (as above in the examples of tree or music type) and 'relational' concepts (see below).

The important point is that secondary stimulus generalization too, however it is called, is a stimulus generalization process even if based on functional, acquired rather than perceptual stimulus equivalence and, as such, is unlikely to fulfil the 'abstract concept' criteria of others such as Chater and Heyes (1994) on the one hand, or Jeffrey Katz and colleagues on the other (e.g. Katz *et al.*, 2007). As mentioned above, categorization explicitly on the basis of abstract concepts as in humans has to be independent of any shared primary or secondary features of the category members. It has to be on the basis of the shared

idea for which all stimuli in the category stand. Abstract concept learning thus cannot be accounted for by Herrnstein *et al.*'s kind of stimulus generalization, or Savage-Rumbaugh *et al.*'s, Urcuioli's or Zentall's kind of secondary generalization processes. It is hence considered a much more difficult cognitive feat, and one school of thought has argued strongly that human-type abstract concepts can only exist in conjunction with symbolic rather than absent/present labelling, that is they depend on language (e.g. Chater and Heyes, 1994).

However, a strong case has also been made for abstract concept learning without language based on judging the relationship between stimuli (see Katz *et al.*, 2007). This would be categorization via 'relational concepts' in Zentall *et al.* (2002). One much-studied example of such abstract stimulus properties is the 'same-different' relationship. In same-different discrimination tasks, animals are tested to see whether they can learn to distinguish pictures ('stimuli', 'exemplars') that show a group of identical symbols ('same') from pictures that contain various symbols ('different'). Animals are first trained on a training set of 'same' and 'different' pictures by conditioning one type of response for 'same' pictures and another response for 'different' pictures. Subsequent transfer of the discrimination to new 'same' and 'different' pictures is taken as evidence that the animals have learnt the abstract concept of 'difference' (or 'sameness').

While much methodological progress has been made in recent years in the study of 'relational concept' learning as abstract concept learning, a number of methodological challenges remain. These include avoiding the use of too few different exemplar pictures in the training set, to give animals a fair chance of acquiring the discrimination, or the use of more than two symbols in each picture, which might enable animals to discriminate based on 'global perceptual features' such as the levels of activity or entropy in the picture (Katz *et al.*, 2007).

Complementary evidence for animals using non-linguistic, yet abstract, concepts when they categorize stimuli may eventually be provided by the neurosciences. Not only have mirror neuron(s) been identified but also - in the pre-motor cortex of macaque monkeys - neurons that are active during hand or mouth movements that involve manipulating or holding objects such as grasping food items, tearing, manipulating or holding them. Importantly, these neurons become active only when the effector movements (i.e. hand or mouth movements) actually result in a different end state from when the movement started; for example, a piece of fruit is *successfully* grasped, or an object is torn apart or flung away (see Gallese, 2003).

Of particular interest here is that some of these neurons are active whenever the monkey achieves a particular end state (e.g. successfully grasps a fruit), regardless of whether the grasping happened with the mouth, left, right or both hands, and that these neurons are located in the brain's *motor* system and might therefore have been expected to fire during effector actions regardless of end state. The fact that these neurons fire when the end state of an action is achieved independently of which effector was used is interpreted as evidence for an 'abstract kind of means-end representation' (Gallese, 2003) - and lies at the heart of Gallese and his colleagues' thesis that abstract concepts can and do arise in the sensory-motor system of non-human brains, and that human, language-dependent concept use 'exploits this pre-existing multi-modal character of the sensory-motor system' (Gallese and Lakoff, 2005).

Conditioning - types of

In the experimental study of animal behaviour, *conditioning* refers to the changes in an animal's behaviour that arise when it learns the association between two correlated events, which we will call Event 1 and Event 2. As the animal learns the Event 1-Event 2 association, the conditioned response emerges in its behavioural repertoire. This response is then observed to extinguish if the original association between events is broken (i.e. if Events 1 and 2 no longer occur together).

Conditioning has been divided into two main types - classical conditioning (also known as Pavlovian conditioning) and **instrumental conditioning** (also known as operant conditioning). The two types of conditioning differ at a basic operational level. In classical conditioning, the animal is exposed to correlations between external events. For example, the animal is presented with a neutral **stimulus** (a **light** or a noise) and this is followed by a biologically important stimulus (e.g. a noxious stimulus such as a shock, or a positive stimulus such as delivery of food). The initially neutral stimulus, known as the conditioned stimulus (CS), comes to provoke a response as a consequence of its being paired temporally with the intrinsically important unconditioned stimulus (US). The classic example of this is the preparation studied by Pavlov himself. Pavlov's dogs would hear a noise (CS) that was reliably followed by delivery of meat powder (US) into the mouth. After several such pairings of the CS and US, the dogs would come to salivate in response to hearing the noise. Salivation would then extinguish if the noise were repeatedly presented to the dogs without subsequent arrival of food.

Instrumental conditioning requires that the animal learns to produce a specified response as a result of its association with a positive or negative US (such as shock or food). For example, in the preparation developed by **Skinner**, hungry rats learn to press a bar (the instrumental or conditioned response) to receive a food pellet (the reward, the US). As in classical conditioning, the response then extinguishes if the US is withheld. In addition to learning to make a specified response (like pressing a bar) to obtain a positive reinforcer (such as food), animals can learn to make such responses to prevent the occurrence of a negative US such as a shock (i.e. a punisher).

In the early part of the 20th century, the separation of classical and instrumental conditioning had as much to do with geography as science. Pavlov and his disciples in Europe were devoted to the study of classical conditioning, while Thorndike and his disciples in North America were almost exclusively interested in instrumental conditioning. However, the two share more than just the term 'conditioning'. In both there must be some contingency between the CS or instrumental response and the US - that is, the two events must be correlated such that the likelihood of the US occurring is increased in the presence of the CS or instrumental response. Thus, conditioning is retarded or prevented if the contingency is reduced by the occurrence of either event without the other (i.e. the CS or instrumental response occurring without the US, or the US occurring without being preceded by the CS or instrumental response). Similarly, conditioning in both cases is sensitive to the contiguity between the events - conditioning is retarded if the temporal gap between the two events is increased. Both are subject to extinction if the US is withheld, and extinguished responding can be seen to recover spontaneously if the animal spends time removed from the experimental apparatus, or if the US is presented on its own (without the CS or instrumental response).

Several theorists have argued that classical and instrumental conditioning are functionally the same, differing only in the experimental procedures employed. The early behaviourists in North America believed that both types of conditioning involved the formation of stimulus-response (S-R) links (e.g. Hull, 1943). According to this view, conditioning involves a simple mechanism whereby, if an animal performs a particular response in the presence of a stimulus and this was followed by a positive outcome, then a connection between the stimulus and response would be formed such that the animal would now be more likely to produce the same behaviour in response to that stimulus. This S-R mechanism was believed to operate whether the response was instrumental or classically conditioned.

However, there is a considerable amount of empirical evidence indicating that any such explanation of classically conditioned responses cannot be correct. One line of evidence is based on the logic that, if these responses were learned because of some putative beneficial outcome, then preventing the animal from producing the response should prevent conditioning. Clearly, this is inevitable in the case of instrumental conditioning - preventing a rat from pressing a bar will prevent it from ever learning that the response produces a reward. However, this has been shown to be false in a variety of classical conditioning paradigms (Mackintosh, 1974). For example, injecting dogs with atropine can prevent them

from salivating and therefore should, according to S-R analysis, prevent them from learning to salivate to a CS (e.g. a noise) that is paired with delivery of food. Several experiments have shown that dogs do, nevertheless, learn the CS-US association, and will immediately salivate to the CS if they are tested after the effects of atropine have worn off.

Many studies have since shown S-R theories to be incorrect in their description of most instances of instrumental conditioning, as well as classical conditioning. One critical source of evidence has been that both instrumental and classically conditioned responses are usually sensitive to changes in the value of the reward (Adams and Dickinson, 1981). For example, if a rat has learned to press a bar for food when hungry, then it will be much less inclined to perform this response when sated for food. This shows that instrumental responses are like an action produced to obtain a particular outcome, rather than being a reflexive response elicited by the sight of the bar (as argued by an S-R account).

P.125

Other experiments have identified a more fundamental distinction between instrumental and classically conditioned responses. This evidence relies on the impact of what is known as an 'omission schedule', where the US is delivered only if the animal does *not* produce the particular response in question (Mackintosh, 1974). Instrumental responses can be eliminated by introduction of an omission schedule. For example, rats that have learned to press a bar to obtain food can readily learn to stop pressing to obtain the same food (if the response-reward contingency is reversed). Classically conditioned responses, on the other hand, are not so flexible. For example, a dog cannot learn to stop salivating to a noise that signals the delivery of food. Similarly, pigeons cannot learn to suppress pecking at a small light that signals the delivery of grain. In each case, if the omission schedule is continued the classically conditioned response will eventually extinguish because the CS is no longer followed by the US. Such findings indicate that, whereas instrumental responses are more flexible and under voluntary control, classically conditioned responses are more reflex-like responses elicited automatically in anticipation of the US.

Confinement

The vast majority of animals kept by man do not stay where humans want them to be unless they are confined to some extent. Hence, the history of animal domestication and usage has involved varying degrees of confinement. If an individual animal learns that a period of confinement is associated with provision of food or other benefits, the confinement itself need not be aversive. However, enforced, prolonged, inescapable confinement will always be aversive and animals indicate this by escaping if possible. The ideal management of animals would involve encouraging them to stay where humans want them, rather than forcing them to do so. Although sheep or cattle on a hillside may be confined by walls, watercourses or cattle grids, and horses in a 20 ha paddock may be confined by fences, the most widely

used meaning of confinement is the restriction of animals to areas where their normal activities are significantly curtailed, and so such situations will be discussed here.

Bears in the wild carry out many different behaviours and range over many square kilometres. Bears in a concrete-floored zoo cage measuring 20 × 20 m are severely restricted in what they can do, and many of their needs are not met, so their welfare is poor. If a group of these zoo bears are given an enclosure that includes a wooded hillside 400 × 400 m, climbing frames, observation platforms, a swimming pool and an indoor sleeping area, most of their needs are met and their welfare is much better than in the bare cage. However, in one zoo where such facilities were provided, the bears still spent a substantial amount of time walking around the perimeter of the enclosure, presumably in order to try to escape. They were still confined and not all of their needs were met. It seems that some animals never adapt fully to even the best zoo conditions, so it can be argued that they should not be kept in zoos. The welfare of rhinoceroses in zoos is often not good, and their breeding record in captivity is poor. However, if they are kept in 50 ha, semi-natural enclosures in their countries of origin, their breeding record is about eight times better, so such conditions, rather than confinement in zoos, should be used if conservation via repopulation of suitable, safe habitats is the objective.

Confinement of animals taken from the wild often results in very poor welfare associated with frantic escape attempts or suppression of all normal behaviour, often followed shortly by death. Yet wild animals are often collected for the pet trade, or for other purposes, then transported over long distances and kept in confinement (**see also: Transport**). Surveys of wild-caught animals transported by air show that mortality of birds, reptiles, amphibians, mammals and fish is often very high. The transport and keeping of wild-caught animals should be allowed only in exceptional circumstances and is never justifiable for pet keeping. If wild animals have to be caught and transported for a more important reason than pet keeping, they should be fully adapted to a captive condition of good quality before use and, for most species, before transport. Zoos should exhibit captive-bred rather than wild-caught animals, and these captive-bred animals should be fully adapted to both the confinement and the exposure to humans which they will experience in the zoo.

Animals kept for fur production, such as foxes or mink, have been bred continuously in captivity for a much shorter time than domestic animals: 40-80 years as compared with 10,000 years or more for dogs, cattle and sheep. Hence, they are changed very little in their characteristics except in respect of colour of fur. It is therefore relevant to know that foxes and mink range over many kilometres, spend time hiding underground, climb frequently, live solitarily for long periods and, in the case of mink, are adapted for swimming and spend time doing so during hunting, playing and exploring. Confinement in a cage less than twice the body length and often not high enough to rear on the hind legs results in poor welfare. The needs of these animals cannot be met in small, wire cages, and these species show abnormal behaviour and other signs of poor welfare in typical fur farm conditions. In good zoo conditions there are few signs of poor welfare, so it appears to be the close confinement per se that causes the greatest problem.

The most severe examples of close confinement, usually temporary, are those used to restrain almost all movements of animals so that they can be examined, treated for disease or moved without risk to human handlers. When mink are put in a metal frame that prevents their movements they show high adrenocortical and other responses, which indicate very poor welfare. Various animals that may be caught and held by humans are also severely affected (**see also: Handling**). Pets transported in small boxes may be substantially affected by the experience. However, the long-term consequences of short-term close confinement may be slight. Some individuals learn from such an experience to avoid or minimize the risk of experiencing it again.

P.126

Among the smallest cages used to confine farm animals are those in which geese and ducks are kept during the period of force feeding prior to slaughter for **foie gras** production. The wire cages allow the

birds to sit or partially stand, with their head protruding through a hole in the top so that they can be force fed and can drink water from a trough in front. In large-scale animal production, one of the smallest space allowances used is that for laying hens in the USA. Many birds are in cages with four or five individuals allowed 350 cm² each. A hen with its feathers in a relaxed position occupies more space than this, so the birds can only fit into the cage if their feathers are compressed. These birds are able to turn around but cannot preen normally or stretch their wings, unless the space allowance is 550 cm² per bird in a five-bird cage. Birds must cooperate by crowding together in order that one of their number has room to show stretching or preening movements. Even with this larger space allowance, which is now required in the European Union (EU), no bird can flap their wings so the hens have insufficient exercise and develop brittle bones (**see also: Bone strength**).

Pens, crates and cages that do not allow individuals to turn around are used for calves, sows and some horses. Each of these animals, plus dairy cows, bulls and many other animals, are sometimes tethered. With the exception of possible adverse effects on the animals of the tether itself, the degree of confinement is often similar in these two circumstances. Animals are prevented from showing normal grooming behaviour if they are unable to reach their hindquarters. They are usually unable to show normal movements during lying down and are completely prevented from showing escape or locomotor behaviour. The use of larger pens for individual animals will, like the smallest ones, prevent animals from showing normal social interactions. Since most social interactions are friendly and some agonistic interactions serve a useful function, prevention of **social behaviour** for the members of a social species is a serious deprivation.

What are the consequences when animals have to live in individual pens or cages that do not provide for their needs? Confined mammals and birds have elaborate control systems that depend upon receiving inputs from environmental cues. If animals lack control because of an inadequate environment, they are likely to use coping methods and to be affected in some ways that we are not able to recognize and others which we can recognize. One consequence is an increase in abnormal behaviour such as **stereotypies**, reduced responsiveness or **self-mutilation**.

One form of stereotypy is route tracing. An animal that is strongly motivated to escape from confinement but which is not able to do so may repeat the locomotor or other pattern of behaviour which might, if not thwarted, have effected escape. Repeated walking over the same route with the same steps is a stereotypy that is readily recognized. Abbreviated movements such as drinker-spout circling in confined rodents, **bar biting** in confined sows and various head and body circling movements in confined mink are all stereotypies which might originally have had a motivation associated with potential escape routes. Other stereotypies shown by confined animals include tongue-rolling in calves kept in crates, crib-biting in horses kept in stables and drinker pressing in sows kept in individual stalls or tethers. The stereotypy is associated with lack of control over the environment and indicates poor **welfare** in the animal. In some cases the stereotypy might help the individual to cope with the environment, but it is likely to be solely pathological in most cases. However, whether or not the confined animal is helped to cope, the stereotypy shows that the individual is having difficulty coping with its environment and hence that its welfare is poor. The stereotypy usually shows that the present environment is lacking in some way, but may be a behaviour that continues after the animal is moved to a better environment. In the latter case the stereotypy is a scar of a previously difficult environment, but it still shows that the welfare of that animal is poor.

There are similar arguments for other abnormal behaviours indicating poor welfare in confined animals - for example, reduced responsiveness to normal stimuli in confined sows, self-mutilation in confined monkeys or parrots and injurious behaviour in confined hens and pigs. Confinement can also lead to substantial adrenal cortical responses, immuno-suppression, reduced reproductive success and early death.

Where confinement prevents normal levels of exercise which an animal is highly motivated to show, restoration of the possibility of carrying out the movements may lead to **rebound behaviour**, in which much of the previously prevented movement is shown as a high priority. Hens kept for a long period in cages that do not allow wing flapping and are then put into a more spacious environment will flap their wings for a long period. This rebound behaviour is shown with a higher priority than eating and drinking. Cattle, sheep and other animals that have been confined during winter periods will show rebound running and jumping when first given access to a field.

As mentioned above, confinement may result in reduced activity and responsiveness. The behavioural, physiological and brain changes associated with confinement have close parallels with depression in humans. Confinement may limit normal behaviour and normal ability to control interactions with the environment in the same way that social constraints can reduce activity and control. It is reasonable to consider many confined animals as being clinically depressed.

Companion animals may be closely confined or kept in small spaces in the ways described above for farm and zoo animals. They may also be free to move around significant usable spaces, such as a house or a garden, but unable to obtain resources or carry out behaviours which are of high value to the individual. A dog or cat that is motivated to hunt for food, social companions or a sexual partner may be prevented from doing this by confinement. Cats kept in houses are certainly deprived of aspects of life which are available to those cats that can leave the house by way of a cat flap.

The welfare of the cat that can leave the house is likely to be improved, although they are at greater risk of being killed on the roads or of being attacked by other cats or by predators. Some cats that are free to leave houses have a very substantial impact on the populations and welfare of wild animals. For example, cats have been found to bring as many as ten rodents and birds per day back to the house where they live. Some of these prey animals will have suffered greatly before being finally killed by the cat. A cat wearing a bell causes less harm. Dogs may also be confined to an extent that their welfare is poor because of lack of companionship from other dogs or from humans. Confinement with another dog as a companion usually causes much less of a problem than confinement in isolation.

P.127

Confinement to a particular area may be brought about by training the individual not to go outside a garden or other area. Dogs are sometimes confined by the wearing of an electric **collar**. This mechanism is so devised that the dog receives an electric pulse if it moves past a certain line. The pulse might be very severe, or it might be just sufficient to allow the dog to learn not to cross the line. The consequences of such a confinement system for animal welfare are very different according to the severity of the current used and the frequency of responses that incur pulses. Farm animals may also be confined by the stimulation they get when they touch an electric fence. Pigs learn rapidly not to touch an electric fence. Indeed, some individuals learn by watching others without ever themselves touching the fence. Such a confinement system can be a good one and have relatively little effect on welfare. However, certain individuals could suffer greatly because of its use. Electric fences have also been used to exclude wild animals as diverse as rabbits and elephants from agricultural areas.

Almost every individual experiences some degree of confinement during life, even if it is only restriction of activity by a parent or by potential danger. However, confinement of any kind makes control of life more difficult, and more extreme confinement leads to such difficulties that welfare is poor. Since confinement of animals used by man may be prolonged, some of the worst effects of humans on animal welfare are associated with confinement. In every case where animals are kept there should be careful consideration of their needs so that adequate resources are provided and harmful confinement is minimized.

Conflict behaviour

When an animal is subjected to a **stressor**, its response may manifest as changes in its behaviour and the physiology of its **autonomic nervous system**, neuroendocrine system and/or **immune system**. Conflict behaviour describes one category of **stress**-induced behaviour changes that arise from conflicting motivations, especially when escape/avoidance responses are not consummated. It can appear as 'a set of responses of varying duration that are usually characterised by hyper-reactivity' (McGreevy *et al.*, 2005). When arising from a relatively brief exposure to a single stressor, these responses typically present as hyper-reactive behaviours such as increased postural tonus, **agonistic behaviours**, redirected **aggression** and displacement activities (Wiepkema, 1987). On the other hand, when conflict behaviours arise from chronic exposure to conflicting stimuli, responses can manifest as repetition and **ritualization** of original conflict behaviours, raised **corticosteroid** concentrations, physiological disturbances and gastric pathology. In addition, **stereotypies** may develop as well as injurious behaviours, such as **self-mutilation**.

Both innate and acquired responses increase an animal's ability to control and predict its 'umwelt', and these serve to avoid conflict. For example, a warning display such as the common mammalian behaviour of pinning the ears back as an aggressive threat is an efficient signal, since it lowers the need for active combat with **conspecifics** during agonistic encounters. Indeed, injury is uncommon during aggressive intraspecific interactions in most species because of the efficiency of such **threat postures**. Animals respond to such threats and are able to flee the stressful situation.

Because of the efficacy of these evolved mechanisms, Moberg (2000) observes that 'it is difficult to envisage a single chronic stressor in non-(captive) animals, with the possible exception of unrelenting pain or prolonged exposure to an extreme environmental condition such as severe cold'. Prolonged motivational conflicts are of great importance in any analysis of animal stress, especially in relation to animals in **captivity** that may be unable to resolve the stressful situation. Conflict behaviours manifest as apparent dysfunctions, in particular stimulus-response entities that reduce predictability and controllability of the environment. However, conflict behaviours may have evolved as adaptive processes to resolve stressful situations.

The term conflict behaviour is appropriate to both interspecific and intraspecific interactions. For example, in human-animal interactions where animals are captive, ridden, led or tethered, there may be no available solution to the imposed stressor. Horse riding is based on negative reinforcement, which comes about through varying degrees of discomfort imposed on the animal by the reins and rider's legs. If the rider incorrectly negatively reinforces undesired or inconsistent responses, or if the rider concurrently

applies pressure via the reins and legs, confusion and conflict behaviours may arise as the horse is unable to resolve the stressful situation. In horse riding, conflict behaviours may manifest as increased aggressive and defensive behaviours, self-mutilation and hyper-reactivity, that ranges from increased muscle tone and body tension to bolting, rearing (standing on the hind legs), bucking (bounding from the hind legs to the forelegs where the hindquarters are kicked up), shying (sudden veering to one side for one or many strides), leaping, flipping over or rushing backwards. It is the responsibility of animal custodians and trainers to understand learning theory well enough to establish desirable learned responses in animals, without causing conflict behaviours. Evaluating problem behaviour in animals in relation to lost predictability and controllability - and the potential conflict that arises from this - is useful in explorations of mismanaged animal training.

Consciousness

Consciousness is instantiated in a wide range of mental states found in humans and higher animals. These states include bodily feelings (e.g. **pain** and pleasure), perceptual sensations (e.g. of sounds, odours and colours) and thoughts, moods and emotions. Consciousness plays an important role in discussions of the **ethics** of animal treatment, because the ability to feel pain and discomfort is one reason why higher animals merit moral consideration.

In both psychology and philosophy, consciousness has proved hard to characterize and even harder to explain. The problem is that conscious mental states seem to be inherently subjective and non-physical. Modern science, in which physics is used to describe the world at the most fundamental level, is not well equipped to deal with such entities. Nor have philosophical attempts to identify conscious states with physical phenomena - such as behaviour patterns or states of the **central nervous system** - been successful. To date, moreover, no one has offered a convincing account about why consciousness evolved.

Simple, causal sensitivity to information (of the sort found in a rudimentary form in ants and bees) would appear to leave mentally endowed creatures as well adapted to their environments as equivalent conscious sensitivity. Why, then, did consciousness develop? This question has encouraged some to regard consciousness as a causally inert phenomenon (**see: Epiphenomenon**).

Conscious states always involve *awareness* of something: I may have a wound on my arm that I am unaware of, but in normal circumstances it makes little sense to say that I have a feeling of pain but am not aware of it. On the other hand, consciousness is not the same thing as awareness, as I may be aware of the spacing of the stairs in my house as I descend them, but not consciously so. Indeed one way of conveying what is special about consciousness is by asking: What is the difference between the awareness in the stair example, which consists principally of an ability to adjust behaviour to the environment, and conscious awareness of the kind involved in noticing that the stair carpet is scarlet, or that one's knee is sore? Very many animal species display awareness of the former kind here. Fewer, presumably, experience the latter.

The problem of providing a scientific account of consciousness can be spelled out with four propositions, each of which seems plausible, but all of which cannot be true.

1. Bodily states and processes are objective and physical in nature, and therefore they have spatial coordinates and can be described and explained in biological, chemical and ultimately physical terms.
2. Conscious states are subjective, lack spatial coordinates and hence cannot be similarly described and explained.
3. Bodily states and conscious states interact, so that if I am pricked with a needle I feel pain and the feeling of pain makes me react.
4. Something with a subjective nature cannot interact with something with an objective nature.

At least one of 1-4 must be rejected, and attempts to solve the problem of consciousness can be classified according to which proposition is denied. Rejecting 4, **René Descartes** (1596-1650) famously embraced interactive dualism and even pointed to a specific organ in the brain, the pineal gland, where he took the interaction to occur. Rejecting 1, Bishop Berkeley (1685-1753) accepted a variety of idealism according to which, in reality, only conscious states exist. But today it would be eccentric, to say the least, to pursue either of these paths. That leaves 2 and 3. The denial of 3 is scarcely credible, although philosophers have certainly toyed with the idea that conscious and bodily states run in parallel, but do not interact, or alternatively with 'epiphenomenalism', i.e. the view that conscious states are epiphenomena brought about by bodily states but lacking causal influence on the physical world (like the sound of a whistle on a steam train, as it is sometimes said).

Contemporary philosophers and scientists are therefore strongly inclined to reject 2 and adopt one or other 'materialist' theory of mind, and the consciousness debate today is really a discussion between advocates of various forms of materialism and critics who doubt that the materialists have succeeded in describing and explaining consciousness. There are several materialist views, of which four shall here be mentioned:

1. **Behaviourism**: conscious states are nothing but dispositions to engage in certain kinds of behaviour. To say that an animal feels hunger is to say no more than that the animal is strongly disposed to eat (this recalls the awareness of the stairs mentioned above).
2. **Reductive materialism**: a conscious state is really nothing but the occurrence of a state in the central nervous system of the organism. For example, the feeling of a certain kind of pain may be identified with the firing of certain kinds of neuron(s) in the prefrontal cortex. However, according to this view

conscious states need not be identified with isolated neural events but may also reflect complex interactions between different parts of the brain.

3. Functionalism: conscious states are physical states of the organism with a functional role. Thus, to have a pain in the right hand is to be in a physical state that causes one to react appropriately, e.g. by avoiding the cause of the pain and doing things that alleviate it. Functionalism combines the insights of behaviourism and reductive materialism. Unlike reductive materialism, however, it allows that conscious states might be found in different kinds of system, not just in organisms with a central nervous system. According to the functionalist, it may be possible for machines to possess consciousness.

4. Strong AI (artificial intelligence): consciousness is related to the body in the same way that a computer program is related to the hardware on which that program runs. Just as one does not need to attribute subjective states to a computer in order to explain how it can run a program, one does not

P.129

need to appeal to conscious states to explain how a human or other animal will act.

According to critics, all forms of materialism suffer from the same problem: they simply ignore the key feature of these states, i.e. that they are subjectively experienced, that the holder of the states is aware of them. A prominent representative of these critics is the American philosopher Thomas Nagel, who argues in a paper entitled 'What is it like to be a bat?' (Nagel, 1974) that what is special about conscious states is that they are essentially tied to the subjective perspective: there is something it is like to experience the colour blue, rather than green, for example, and this is not captured in materialist theories of mind.

However, it is one thing to criticize materialist accounts of consciousness and another is to come up with a better approach. And here the critics have been less helpful. Another prominent critic, the American philosopher John Searle, claims that a solution to the problem cannot be given until science develops a new, and richer, way to describe biological phenomena that cuts across the present distinctions between objective and subjective states. Other philosophers claim that it is part of the human predicament that we are unable to solve the problem of consciousness.

The upshot is that applied ethologists, who are required to obtain science-based information about the conscious states of animals in connection with, for example, enquiries into animal welfare, are left in a very difficult situation. They cannot directly study the conscious states of animals - they must use objective parameters that they can interpret as signs of the conscious states they are investigating.

Conservation

Conservation may be defined as either: (i) the act or process of conserving, the careful guarding of an asset (biodiversity, beauty, heritage, ecological processes, evolutionary processes); (ii) preservation or restoration from loss, damage, deterioration or neglect; or (iii) the improvement of our natural resources and environment. It implies the preservation and careful management of the environment and of natural resources in a given place (particular habitat, ecosystem, biome, biosphere as a whole). Recognizing the urgency of the global ecological crisis, conservation aims actively to improve by preventing loss, injury or other change of a population, community or ecosystem.

Social and ecological structures and processes are interrelated. Society has an impact on the environment, and therefore conservation aims to influence society's impact and the way that it interacts with nature and **biodiversity**, by promoting solutions through research, consultation, education and partnerships. Conservation is necessary because every living thing depends on other creatures. Together they form a community, a living web, in which all strands contribute to the stability of the whole. Conservation aims to prevent **extinction**, a process of population decline (i.e. endangerment) that reaches the end point of complete disappearance from Earth, causing losses of genes, adaptations and ecosystem processes even before the actual complete disappearance occurs. **Endangered species** exist in low population numbers and need intensive long-term management in order to survive. Endangerment is a broad issue, one that involves the habitats and environments where species live and interact with one another. Although some measures are being taken to help specific cases of endangerment, the universal problem cannot be solved until humans protect the natural environments where endangered species dwell.

Conservation biology, originally a branch of biology that deals with the effects of humans on the environment and biological diversity conservation (endangerment), now broadens its scope to the consequences of biodiversity loss to human and biosphere survival. Conservation biology priorities are: (i) to stop the degradation of the planet's natural environment and build a future in which humans live in harmony with nature; (ii) conserve the world's biological diversity; and (iii) ensure that the use of renewable natural resources is sustainable by promoting pollution reduction and reducing wasteful consumption.

Reasons for conservation

While the idea of conserving the environment has steadily gained political acceptance over the past few decades, people still misunderstand and ignore the goods and services that nature, biodiversity and ecosystems provide to humans. For example, 15,589 species of animals and plants are threatened with extinction and many ecosystems, including wetlands and forests, are being degraded and destroyed, even though these ecosystems provide humans with a large range of highly valuable services. The importance of well-functioning ecosystems in helping reduce poverty and improve livelihoods, societies and economies is increasingly clear to scientists and to society. This knowledge needs to be integrated into the decisions and actions of local, national and international policy makers in all sectors, as well as business leaders.

To achieve effective biodiversity conservation, one prime activity for scientists is to contribute to the understanding of what natural ecosystems provide to humans. But conservationists should also seek to

ensure that this knowledge is used in practical ways by bringing together scientists, policy makers, business leaders and non-governmental organizations (NGOs) to impact the way the world values and uses nature. Only in this way will Earth's natural heritage be maintained for future generations, allowing them to thrive spiritually, culturally and economically.

A conservationist's mission is to conserve the Earth's living heritage and global biodiversity, and to demonstrate that human societies are able to live harmoniously with nature, saving wildlife and wild lands through careful science, international conservation and education.

P.130

The emergence of conservation biology

Conservation biology is the study and preservation of habitat for the purpose of conserving biodiversity. The term 'conservation biology' refers to the science, and is sometimes used also to encompass the application of this science. In simple terms, conservation biology is the scientific study of the phenomena that affect the maintenance, loss and restoration of biological diversity. Its research integrates biological with economic, anthropological, legal and other social science perspectives. Conservation biology has only recently begun to address the **ethics** of protecting biodiversity. Conservation biology provides scientific expertise to support the conservation and recovery of biological diversity in its natural state through applied research, education, planning and community service. Philosophically, the concern of this branch of biology is generally to help save the diversity of life on Earth through applied conservation research.

In the realm of research, biologists seek creative and effective ways to address a wide diversity of ecological problems, ranging from endangered species population decline to regional conservation planning for ecosystem conservation. This translates into developing better conservation tools, analyses and techniques. A practical aim of the whole field is to stop human-induced extinction. Conservation biology requires conservationists to implement conservation actions. The reasons for extinction are changing: in prehistoric times, natural disasters and competition with other species were the main causes; in historic times, overexploitation and **exotic species** introductions caused many extinctions. But today, the main problems facing wildlife are destruction of habitat and pollution. Conservation uses an array of tools to describe the phenomena that affect the maintenance, loss and restoration of biological diversity. As a consequence of proper conservation actions environmental health, economic vitality and informed land use decisions can be achieved. In practice, conservation actions are oriented at preserving the plants, animals and natural communities that represent the diversity of life on Earth, by protecting the lands and waters they need to survive.

A conservationist is someone who works to protect species from extinction, but little attention has been paid to the fact that populations are composed of individuals (see Fig. C.9). A population decline is somehow described as an ecological phenomenon caused by humans, but how this decline operates in individuals by affecting their behaviour, physiology and welfare is often neglected or unknown. Any process that affects species is indeed affecting the individuals of a given population. **Hunting**, habitat destruction, pollution or introduced species are significant animal **welfare** factors affecting individuals and triggering stress responses. Long-term **stress** and distress factors caused by conservation problems are likely to produce suffering, pain, behavioural problems or displacement.

Conservationists tend to focus on population trends (i.e. decline), and they have historically paid little attention to animal welfare. In fact, the decline of any given population is preceded by animal welfare problems and the link between both disciplines, although it should seem obvious, is not clearly understood by conservation biologists. Population decline is a mere symptom of an animal welfare problem. Wildlife harassment and habitat destruction (e.g. fire, land degradation, toxic waste, oil spills) are both suffering and distress factors affecting individuals, and direct mortality, injuries, diseases and behavioural perturbations are all clear signs of animal welfare consequences. An animal welfare approach to

conservation biology underpins a more thorough and accurate understanding of the prime causes of population decline (i.e. conservation problems).

There appears to be a dichotomy between animal welfare and conservation biology. While conservation biology focuses on population decline in a given environment (reflecting the interdependence of all living things and prioritizing the population, community and ecosystem levels), animal welfare focuses on selected wild species' life history and fate as a consequence of human pressure (directly or indirectly). In fact, there are many rifts and disparities between these two groups, both in practice and at a theoretical level. Like conservation biology, the emerging field of animal welfare is increasingly becoming an area of immense interest and inquiry in the general discipline of wildlife management and environmental sciences.

The sciences of conservation biology and animal welfare have traditionally been conducted in two independent spheres. Conservation biology, a discipline focused on the causes of population decline and the study of extinction caused by human actions, has traditionally been the realm of ecologists and biologists. Animal welfare, on the other hand, is defined as the state of an individual animal or wild population in relation to its ability to cope with its environment, and has traditionally been the niche of physiologists, ethicists, behaviourists and veterinarians. Thus animal welfare scientists measure factors that may contribute to good or poor welfare, or measure physiological and behavioural states believed to reflect good/poor welfare in wild animals. Conservation biologists are concerned about the causes of population decline such as habitat destruction, human pressure and the effect of alien species. Priorities are set at different thresholds (see Fig. C.10). While conservationists pay attention to species that are already declining (a symptom), animal welfare scientists are focused on how different species react to human-induced stress (the cause). A meeting point for both disciplines is in endangered

P.131

species, where only a few survive and rescue actions and management practices such as **translocation**, **captive breeding** or anti-poaching protection activities are prime tools for both disciplines.

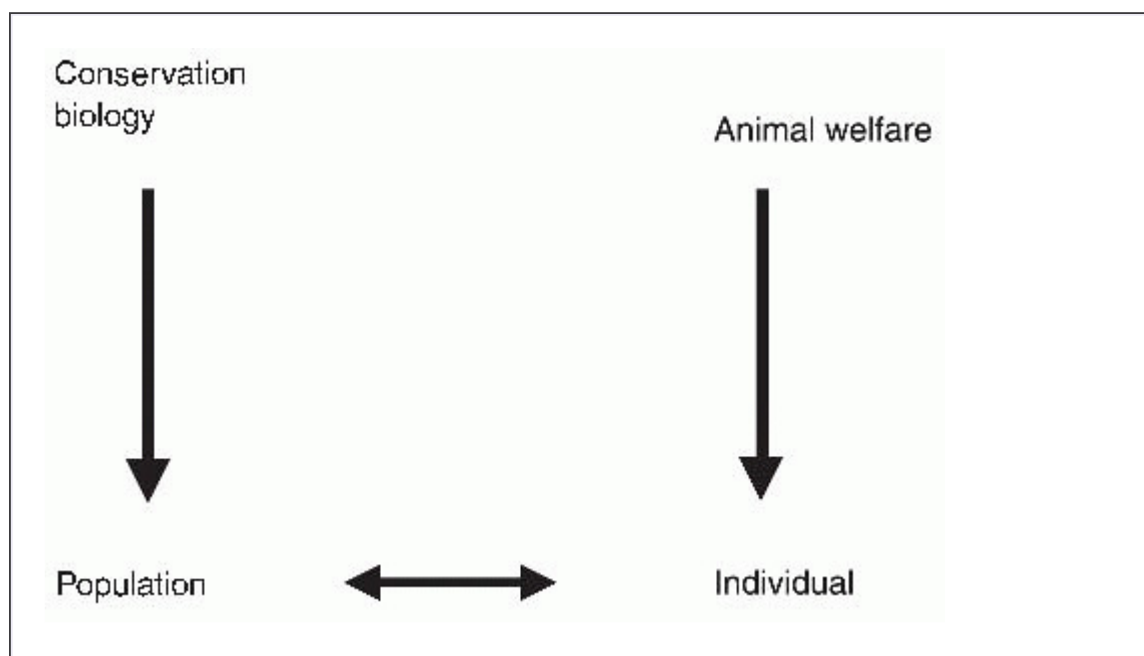

Fig. C.9. The mismatch between conservation and animal welfare approaches: an actual mismatch of priorities between animal welfare scientists and conservation biologists that can be solved by understanding that human-induced stress is a prime factor common to both disciplines.

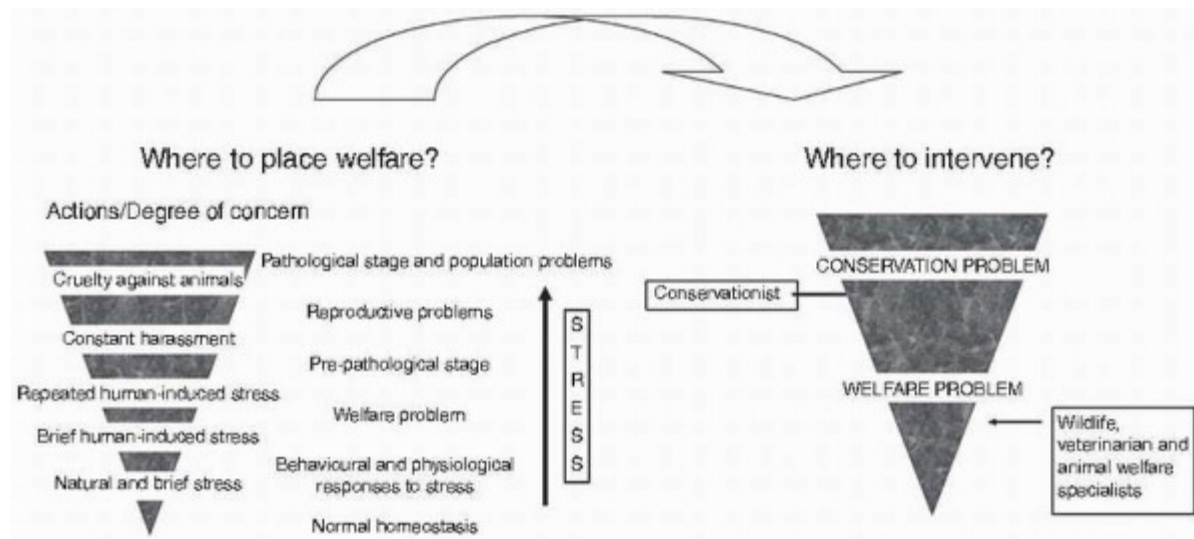

Fig. C.10. The critical point of intervention for a wild animal: an animal welfare perspective - a conservationist threshold that 'activates' their concern about a given species related to the diagnosis that population decline is occurring. An animal welfare scientist should intervene even before population decline occurs, by preventing the stress that causes welfare problems. Any natural stress or human-induced stress is not considered a conservation or animal welfare issue until it effectively becomes a repeated, long-lasting stress or distress that might drive the individual into the pre-pathological, reproductive or dead stage, when a population decline effect may be observed.

On the other hand, animal welfarists and conservation biologists are in conflict when culling, hunting quotas or control techniques for invasive species are discussed as conservation tools. While conservationists' main priorities are to restrict ecological damage at any price, animal welfarists are concerned about the consequences of control, hunting, culling or sustainable use on the individual. This kind of issue gives rise to distrust and controversy and contributes little to the development of a common ground for both disciplines.

Although the approach to the species problem may seem different, ultimately both disciplines are focused on the direct or indirect effect of humans on wildlife. Moreover, both conservation biology and animal welfare are multidisciplinary, 'goal oriented' and based on the **precautionary principle**. It seems that the reasons for both disciplines to be separated are more related to lack of understanding of a common language than to differences in their ultimate goals.

Currently, society is asking for solutions to the biodiversity crisis, and animal welfare-oriented funding is contributing to wildlife conservation worldwide. It seems that the inclusion of animal welfare approaches is enriching the conservation biologist's tool kit for a better approach to conservation that integrates

increasing societal demands. The dichotomy between individual- and population-level work can actually be detrimental to a full understanding of many life history processes affected by human disturbance.

Both conservation biology and animal welfare are based on ethical considerations of how humans interact with other non-human animals and the environment. The claim that we have ethical obligations to animals and their environment is valid and common to both disciplines, and it has been argued that animal welfare considerations should be incorporated into conservation policies (e.g. trapping standards, captivity recommendations, etc.). The fact that welfare is usually measured on an individual basis, whereas some wider goals of conservation are measured on populations, does not make them incompatible. Indeed, new assessment methods and more refined research approaches allow us to understand the ultimate causes of population decline (e.g. **biotelemetry**, **stress hormones** in faeces, video tracking of abnormal behaviours). Moreover, in many cases population decline can be explained by understanding behavioural and physiological changes that are the main realm of animal welfare science. Both disciplines are now crucial to understanding how to recover endangered species, conserve wildlife, control invasive species in a humane manner and solve conflicts between people and wildlife. The inclusion of animal welfare science into conservation biology is an opportunity to enhance research methods currently in use to understand population decline while meeting the ethical needs of our societies, demanding not only environmental protection but also proper care for wild species.

Conservation behaviour

Conservation behaviour is an emerging discipline, founded largely by behavioural ecologists (**see: Behavioural ecology**) who attempt to use behavioural research and theory to solve conservation problems facing diminishing animal populations in today's world. It differs from other areas of applied animal

P.132

behaviour both because its roots are in the more theoretical approach adopted by behavioural ecologists and because its focus is predominantly on **conservation** in the wild. A series of influential books and papers since the end of the 20th century have spoken of the many implications that behaviour - particularly behavioural ecology - has for conservation.

That the behaviour of animals influences conservation is a truism, but the challenge for behavioural scientists has been to move from the *implications* phase of conservation behaviour to more active *applications* to solve real-world conservation problems. Past efforts have, perhaps, overemphasized function at the expense of proximate mechanisms. While a functional approach does afford testable hypotheses that can guide conservation behaviour research, it is the proximate mechanisms that can be manipulated in the service of conservation needs. Recent developments, however, have begun to synthesize the more mechanistic approach of applied ethologists and comparative psychologists (**see: Comparative psychology**) with the functional approach of behavioural ecologists, promising an increase in the conservation applications of the discipline.

Conservation behaviourists have identified several behavioural topics that are especially important for conservation application. In small populations - captive or wild - human intervention is becoming increasingly necessary to manipulate **social behaviour** and **reproductive behaviour**, to encourage breeding or to enhance the persistence of genetic diversity. Some conservation behaviour research strives to identify the right combination and density of individuals to get animals breeding. A great deal of research also addresses mating strategies, because some mating patterns can lead to loss of genetic diversity if individuals are over- or under-represented. For example, if one male is dominant or preferred by females, he can sire many offspring, while subordinate or less preferred males may leave behind no

offspring. In small populations the loss of this genetic diversity can cause crippling inbreeding depression. Recent experiments have shown that it is possible to manipulate these outcomes and equalize breeding opportunities among competing males. Because animals use displays and signals to compete and court, studies of communication processes have been instrumental in solving this problem.

Several other topics are addressed by proponents of conservation behaviour. Foremost among these, perhaps, is dispersal and habitat selection. Understanding these behavioural processes is critical for designing reserves that contain the necessary resources and allow natural dispersal to take place. In most species the young of one sex disperses out of its natal area and settles far from its birthplace, thus avoiding inbreeding with its relatives. As habitat becomes increasingly fragmented, however, animals may not be willing to disperse across human-altered landscapes. Dispersal is a risky period in an animal's life, and dispersers must assess various aspects of habitat suitability and make a decision regarding where to settle. It is important to understand these behavioural processes to predict the potential effects that human activities - including conservation management - may have on animal populations.

Reintroduction programmes also rely - or should rely - heavily on behavioural research and may be the best-developed application of conservation behaviour research. Reintroduction involves the captive breeding and release of individuals into the wild or the translocation of wild animals from one location to another. These actions create major challenges for the welfare and survival of animals released into completely novel environments. While they are a worthwhile conservation action, these measures require comprehensive research programmes addressing many facets of behaviour to predict likely outcomes, devise optimal strategies and monitor individuals following release.

These are just a few of the activities pursued by conservation behaviourists. Others include human disturbance, human-animal conflict - such as crop raiding and livestock depredation - behavioural responses to invasive species and many more. Behavioural research is nowadays playing an increasing role in mitigating these emerging conservation crises.

Conservation centre

There is no agreed-upon definition for what a conservation centre is or should be. The term 'centre' seems to confine the usage of this term to conservation programmes that are based primarily in a single

geographic location. Thus, many major conservation organizations, such as The Nature Conservancy or World Wildlife Fund, are not considered conservation centres, although they may manage many such centres as part of their conservation effort.

Popular use of the term includes environmental education programmes or **ecotourism** vacation packages. Here, one might expect to see miles of hiking trails with an interpretive centre carrying a **conservation** message. Animal rehabilitation centres are another common form of conservation centre. In these, local wildlife is rescued, cared for and sometimes released back to the wild. Often, rehabilitation centres are more focused on individual animal welfare and may contribute little to the conservation of the species in the wild and, in at least a few cases, may compromise wild populations if releases are well-intentioned, but ill-conceived. For example, released animals may introduce disease, cause social disruption or reintroduce tame animals that will increase human-animal conflict. Many conservation centres are devoted to the conservation of a single species or a group of related species, such as **gorillas**, crocodiles or parrots.

Captive breeding programmes are another widespread form of conservation centre. Often run by government organizations, non-profit non-governmental organizations or zoos, these programmes usually maintain the goal of breeding

P.133

endangered species as a hedge against **extinction** in the wild and to provide candidates for release back to the wild. The new zoo ethic embraces conservation, and thus zoos are a fast-growing type of conservation centre. Many of the larger zoos - such as the Zoological Society of London and the Bronx (New York) Zoo's Wildlife Conservation Society - support programmes that integrate animal exhibition, captive breeding, field conservation and education. The San Diego (California) Zoo's Conservation Research Center, for example, espouses a mission to generate, share and apply scientific knowledge vital to the conservation of animals, plants and habitats. As part of a multidisciplinary effort, this centre targets several key areas in conservation, including sustainable populations, bioresource banking (the frozen zoo), wildlife health, habitat conservation, restoration biology and conservation education.

Conservation centres encompass a diversity of approaches but, as the label suggests, the term should be earned by making some meaningful contributions to conservation through a combination of activities such as protection of animals and landscapes, breeding programmes or research.

Conspecific

A conspecific is a member of the same species. The provision of conspecific company is considered especially important when assessing the **welfare** of an individual member of a social species. However, the extent to which conspecifics are appreciated as such is dependent, not least, on **socialization** and **filial imprinting**.

(PDM)

Conspecific attraction

Conspecific attraction describes the tendency of some animals to settle near individuals of their own species. It corresponds to an aggregation phenomenon which is beyond the density variation predicted by the quality of the environment. This behavioural phenomenon is particularly well known in colonial species such as seabirds, but recent studies have shown that conspecific attraction is widely distributed among a range of other, less social, species.

The conspecific attraction hypothesis suggests that, in many species, dispersing individuals looking for a place to settle and establish a new home will rely on the presence of **conspecifics** to assess habitat suitability. The general concept of conspecific attraction has been recognized outside the scientific community for generations. For example, hunters have long used duck decoys to attract ducks to a pond. Presumably the presence of these decoys falsely advertises that this is a safe place with good resources.

Judy Stamps of the University of California, Davis is largely responsible for developing and refining this concept in the scientific literature. In the 1980s she proposed that, even in relatively solitary, territorial species, habitat settlement was socially facilitated. Ecologists had long believed in the 'ideal free distribution' of animals in the landscape, wherein population density directly reflected habitat quality. Dispersing individuals were envisioned to settle in the most suitable habitat and to avoid settling in close proximity to conspecifics, which were thought of as competitors for resources. Territories should clump close together only where density of resources was high. Controlling for habitat quality, Stamps found that *Anolis* lizards actively preferred to settle adjacent to conspecifics and proposed that dispersers used the presence of conspecifics as cues to territory quality. Taking a more behavioural perspective than that of ecologists, Stamps suggested that dispersing individuals lack knowledge of habitat suitability, and could most easily assess habitat quality by its correlation with the presence of other conspecifics. Thus, dispersers may follow the rule of thumb that, if other conspecifics are present, then the area must be relatively safe and contain appropriate resources. Since this hypothesis was proposed, tests in a variety of vertebrate species have supported the notion that conspecific attraction is a widely distributed behavioural phenomenon, even in relatively asocial species.

This concept has profound implications for conservation. Ecologists regularly use animal density as an index of habitat preference, but the conspecific attraction hypothesis clearly suggests that patterns of animal density on the landscape may be unrelated to habitat suitability. This is increasingly true in human-altered landscapes. Animals may be pushed into marginal habitats or extirpated in areas of prime habitat suitability. Dispersers may choose to settle next to members of their own species in suboptimal habitat, and may even reject habitat that is more suitable for the species if conspecifics are absent. Thus, studies correlating the presence of a species with the habitat in which it is found may be misleading.

These observations pose a problem for conservation managers attempting to recruit animals into suitable habitat, such as newly created protected areas. If the species has been eradicated in the area, animals may not recolonize it through natural dispersal. If animals are reintroduced there they may not settle, instead choosing to disperse to another area where conspecifics can be found. This may be one explanation for why so many **reintroduction** programmes fail: released animals following simple behavioural rules of thumb for habitat selection and settlement may choose not to stay in a habitat that is perfectly suitable. It goes without saying that this kind of disruption, including risky and stressful long-distance dispersal, can also have significant **welfare** consequences. Thus, research to facilitate speedy settlement in suitable habitat has both welfare and conservation implications.

A promising strategy for addressing this problem is for conservation behaviourists to conduct research towards an understanding of the behavioural mechanisms underlying habitat settlement rules. Earlier studies have shown that the presence of actual individuals may not be necessary for conspecific attraction

to operate. For example, playback of birdsong can attract territorial bird species to settle in unoccupied habitat. The key then is to understand which **signals** animals use to identify the presence of conspecifics and how they find ways of manipulating these signals to encourage settlement.

Recent research is beginning to tap into this realization, and the settlement patterns have been managed for conservation

P.134

purposes in several species. Decoy models capitalizing on visual cues have been used to attract colonially nesting seabirds to safe places. In some cases simpler visual cues can be used. For example, griffon vultures can be attracted to new breeding sites by painting cliffs with white paint, imitating the accumulation of faeces. Grouse can be induced to establish new **lek** sites using acoustic playbacks of vocalizations. The role of olfactory signals in habitat settlement is less explored, as is the usefulness of this technique in manipulating the behaviour of mammals. Recent research, however, shows that translocated black rhino can be induced to settle next to 'virtual scent territories' by spreading conspecific dung in a way that mimics natural dung-marking patterns. For denning species, such as bears, olfactory cues may prove useful for attracting animals to safe denning sites in the same way that visual cues have worked to attract birds to nesting sites.

Behavioural researchers are only beginning to test the utility of applying such behavioural and ecological concepts to conservation management, but initial results suggest great promise for further study of conspecific attraction in a conservation context.

Consummatory acts

Consummatory acts are characterized as being the relatively stereotyped actions occurring at the end of a behavioural sequence. Although ingestion of food and water may be consummatory acts, consummatory acts can include copulation, burrow digging and many other activities. Consummatory acts should not be confused with **modal action patterns** or fixed action patterns, **instinctive behaviour**, **innate** behaviour, **operants** or **reflexes**, although they may include such phenomena. The term 'consummatory act' was central to classical ethology, but became less so beginning in the 1970s as ethology was influenced by behavioural ecology and adaptationist thinking, the proponents of which were relatively uninterested in behavioural mechanisms. None the less, with the renewed interest in the control and organization of behaviour in animal cognition, behavioural neuroscience and applied areas such as conservation and

captive animal welfare, the ideas underlying the concept are increasingly recognized as being both relevant and useful.

The term 'consummatory act' was first popularized, if not coined, by Wallace Craig in a classic paper published in 1918 (Craig, 1918). It was initially proposed as an attempt to systematize our thinking about behavioural organization, particularly the normally occurring instinctive sequences found in the behaviour of both human and non-human animals. The term nominally refers to a behaviour action, such as a bite or copulation, that follows **appetitive behaviour**, and thus cannot be effectively discussed separately from appetitive behaviour. In brief the sequence is as follows. A **motivational state** derived from a **need** or **drive** instigates the animal to engage in, typically, locomotor behaviour to locate important stimuli such as food, prey, a mate, or a nesting site. This *appetitive behaviour* is typically highly variable and may involve a variety of orientation processes as well as learning (using past experience) to locate such stimuli. **When** the stimulus is encountered, behaviour is elicited that leads to the performance of relatively stereotyped acts such as prey strikes and prey handling, copulation, burrowing, or even retrieving and splitting nesting material. The performance of these *consummatory acts* typically leads to the satisfying of biological needs, and are then followed by the third phase, *relative rest*. Aversions to dangerous stimuli involving predators or **conspecifics** would be handled similarly, involving flight or other anti-predator response such as freezing, crypsis, threatening, attacking, etc.

The actual sequential organization of behaviour is often more complex, of course, as more than one motivational system may be involved (Burghardt, 1973). Behaviour systems theory (Timberlake, 2001) is an updated version of the original conceptual framework developed by Craig and extended by other ethologists (e.g. Lorenz, 1981). In male stickleback fish reproductive behaviour, numerous consummatory acts have been described including chasing, biting, digging, gluing nest material, zigzag dancing, quivering and fanning eggs.

The usefulness of the separation of appetitive behaviour from consummatory acts was in the resolution of two apparently conflicting ways of looking at instinct. For zoologists, typically, instincts were highly stereotyped innate responses shaped by natural selection and largely impervious to any important role for individual learning. Psychologists, on the other hand, were more likely to view instincts as motivational factors leading to general biologically useful outcomes (e.g. **hunting**, eating, mating and fighting). The details of the instincts were thus quite open to learning and experience, especially in the mammals that psychologists were most inclined to study.

The sequential separation of appetitive behaviour and consummatory acts showed that both approaches were valid, but generally in different places in the sequence. Thus, almost all learning studies involve altering appetitive behaviour - mazes, problem boxes, operant conditioning, discrimination learning - even observational learning and imitation. What is modified is rarely the performance of the behaviours involved in responding to the attained 'rewards' such as eating, drinking or mating. Lesioning and other neural studies support the differentiation of consummatory and appetitive behaviour at both the neural and conceptual levels (Burghardt, 1973; Balthazart *et al.*, 1998). Arousal mechanisms, for example, have long been separated from copulatory mechanisms in studies of hormones and **sexual behaviour**.

One interesting aspect of consummatory acts is that animals often find the mere performance of the act, and the sensory stimulation involved, reinforcing, separate from **feedback** from the biological needs being satisfied. Mating is a clear

P.135

example, but studies show that animals often stop eating or drinking long before the food or liquid has had its requisite physiological effect. This may be true of many other behaviours as well, and thus the opportunity to perform species-typical consummatory acts may be an important component of an effective incorporation of animal welfare concerns into captive management (Hughes and Duncan, 1988). It is also apparent that the quality of the stimulus responded to can either suppress or enhance

performance of consummatory acts. This is a factor in feeding and weight regulation in many animals. More palatable food, regardless of nutritional value, is ingested more than less palatable items, and it has been suggested that this can lead to obesity in captive animal, pets and people, although some argue that the balance of nutrients is more important in this problem. In farm animals at least, it seems that palatability is more important in initial acceptability, i.e. initiation of the consummatory act, than total intake, i.e. its persistence. The role of feedback thus needs to be evaluated in terms of both internal (physiological) and behavioural performance factors.

It is commonly noted that captive animals, especially without previous experience with normal stimuli, sometimes perform consummatory acts to an abnormal stimulus when deprived of species-typical stimuli. Such behaviour is often seen in predatory and mating behaviour, where stalking and mating attempts may occur towards alien species or even inanimate stimuli. Occurrence of such phenomena in captive animals need to be diligently recorded, as these may underlie many compulsively performed stereotypic behaviours found in captive animals, especially those kept in small or sterile enclosures.

Many studies show that experiences can alter some details of consummatory acts such as eating and mating behaviour, just as it takes some skill for people to learn how to use a spoon or chopsticks. However, the truly final end of instinctive sequences, such as swallowing food, sucking at the breast or thrusting in copulation is still largely stereotyped within a species, as compared with the appetitive phase.

Inexperienced animals, although highly motivated to perform, are often awkward and unsuccessful, but none the less they persist. **Play** behaviour may be a prime area in which consummatory acts are explored. For example, many animals manipulate objects using predatory movements (jumping, grabbing, biting, manipulating) but refrain from the final consummatory acts of ingestion. Similarly, in play fighting many movements are seen except for those that could truly injure or kill the opponent - or, more accurately, play partner. Play behaviour is often more often observed in well-cared for captive animals, and this may be due to the activation of one or more behaviour sequences in contexts not essential for survival.

Contiguity

Contiguity describes the closeness of the relationship in either time (temporal contiguity) or space (spatial contiguity) between two events. In the original Laws of Association as applied to learning it is proposed that events that are highly contiguous are easily associated through learning, as are events that are more frequently associated or associated with an emotional consequence. However, more recent research has suggested that **contingency** (predictive value of one event relative to another) may be of more relevance than contiguity in predicting learning outcome. For example, events that are presented simultaneously are not necessarily easily associated, contrary to what the law of contiguity would suggest, and events that are not necessarily highly contiguous may be associated if one event reliably predicts another.

(DSM)

Contingency

Contingency describes either the extent to which one event predicts another or to what extent the two events covary. The graphical representation of this relationship is referred to as a contingency space (see Fig. C.11). The contingency between events is important in predicting learning of the association.

Stimulus-contingent events occur only if a given stimulus is present (e.g. the delivery of food into the dog's food bowl when you call the dog for its meal), while response-contingent events only occur if a given response occurs (e.g. the dog is rewarded for coming when called only if it comes promptly).

Contractarianism

According to the ethical position, contractarianism morality reflects a tacit agreement between *rational* agents who, motivated by self-interest, agree to rules or principles that indicate acceptable behaviour. This precludes animals, however. There is ongoing debate about whether dependency and reciprocity, instead of rationality or self-interest, should be the basis of an interspecific social contract.

(RA)

Contra-freeloading

Contra-freeloading describes the phenomenon whereby an animal will work for a resource, in preference to accessing the same resource without work. The phenomenon has been reported as occurring in virtually all vertebrate species

P.136

investigated, with the possible exception of the domestic cat, although variation may occur between different breeds. Some studies that have claimed to investigate contra-freeloading using environmental

enrichment devices have been criticized as a different food is offered in the enrichment device, which confounds the investigation.

The phenomenon is problematic to animal behaviour scientists, as it appears upon initial consideration to contradict traditional models of **motivation**, learning and **optimal foraging**. However it has been found that the tendency to contra-freeload declines with hunger and with an increased work effort, and that sensory reinforcement may be an important component of the process. Animals may choose to work for a resource in order to obtain additional information that is not available if only the free source is chosen

(information gain hypothesis). This may have adaptive value as the animal learns about access to alternative food sources should the free source become unavailable. Thus it would seem erroneous to conclude from contra-free-loading studies that animals prefer to work for food, but rather that they will work to obtain information, and that food-based environmental enrichment devices do not necessarily improve welfare because they do not provide that information.

Control - experimental

Research experiments are set up to investigate the effect of one variable at a time, and any measured effect is compared with animals that have not been so 'treated' - the controls. Controls may be given no treatment at all, or be given everything except what is under test, e.g. a new drug. A control may therefore be administered the same dosage regime but given the excipient (carrier solution or vehicle). A sham operation is another form of control where the same surgical procedure is used, except that an experimentally crucial part is omitted. On other occasions the control may be the best contemporary treatment, so that a new drug is compared with those drugs that are currently in use to treat a particular disease. Sometimes controls are used to make sure that the experimental test group is valid, e.g. a positive control might be run to ensure that a frozen-thawed microbiological culture was still virulent in a challenge test with a new batch of vaccine.

(DBM)

Controllability

It has been suggested that the impact of an environmental challenge depends not only on its intensity and duration, but also on its predictability and controllability. In a classic experiment by Weiss (1972), pairs of rats were separated but had the same electric current applied to their tail at certain times. One of the pair had some control over the delivery of the shocks and some way of predicting and controlling the current, by pressing a lever when a light flashed, while for the other this cue and response had no value. Those without control or a way of predicting the shocks exhibited a much greater **stress** response. Similarly, a reduced predictability and controllability of positive events may also lead to a greater stress response.

Predictability is not necessarily linked to controllability; for example, food may be delivered according to a highly predictable schedule for animals in captivity, but it may have no control over the delivery of that food. It has been suggested that controllability may explain the phenomenon of **contra-free-loading**, although this explanation has been rejected by many. Environments with a high level of predictability and

control are not necessarily beneficial to an animal's well-being because, although they may reflect certainty in the environment, they also suggest a lack of novelty. Given that higher animals have evolved in response to the pressures of a changing environment, it is suggested that their physiological systems may be adapted (both phylogenetically and onto-genetically)

P.137

to function most efficiently within an environment with some level of unpredictability and uncontrollability, although there is no universal optimal value.

Convergent evolution

This term describes the evolution of superficially similar (analogous) structures or behaviours in two or more distantly related lineages that have arisen through adaptation to similar ecological conditions rather than through shared, common ancestry. For example, the wings of a bat and a bird are similar, despite the fact that a bat is more closely related to a whale than it is to a bird. Thus, wings in these two groups have evolved independently (in parallel) yet serve similar functions. A classic example is the physical similarity between marsupial and placental mammals despite the fact that the two lineages have evolved independently on separate continents: the placental anteater and the marsupial anteater (numbat), the Tasmanian wolf and the placental wolf, the marsupial mole and the placental mole, and the flying squirrel (placental) and the flying phalanger (marsupial).

(PE)

Cooperation

Cooperation is a voluntary act in which two or more individuals work together to bring about an end situation with greater benefits than they could have obtained by working individually. In cooperation, benefits to the individuals working together exceed the costs. African wild dogs (*Lycaon pictus*), travelling in a pack across the Serengeti, will spot a grazing gazelle and organize themselves around the prey. As the gazelle flees the approaching dogs, the pack will spread out around it so that a sudden turn or misdirection will give one dog a chance to intercept. While one dog grabs the gazelle by the nose, others attack from behind. Successful predations such as this will only occur through cooperative effort. In captive chimpanzees (*Pan troglodytes*), individuals often groom each other for long periods of time. If the chimpanzee group is fed later in the day, the groomer may solicit their friend for food. The latter will show greater tolerance than they would have without the previous **grooming**.

Table C.4. Cooperation delineated into different types based on category of genetic relationship (kin versus non-kin).

Subjects	Cooperation		
	Form	Description	Example
Related individuals	Kin selection	Cooperation dependent on the relatedness of the individuals involved; the closer their relatedness, the lower the effort needed to overcome the cost of cooperating	Eusociality in insects, where sisters cooperate to raise and defend the colony's young
Unrelated individuals	Mutualism	The benefits of cooperation are collected simultaneously by all parties	Cleaner fish eat ectoparasites off larger fish, which benefits both parties at the same time with, respectively, food and a reduced parasite load
	Reciprocal altruism	All the benefits of cooperation go to the partner, who reciprocates on a later occasion	Chimpanzee food for grooming exchanges in which the recipient of grooming later tolerates taking of food by the groomer

In a natural world in which every individual is considered most interested in its own survival and reproduction ('nature red in tooth and claw', as Alfred Tennyson put it), cooperation represents a puzzle. Why cooperation evolved is a central issue in evolutionary biology, which classifies it into two distinct types depending on the genetic relatedness among the cooperating parties. The first type, cooperation among related individuals, is probably the product of **kin selection**. The second, cooperation between unrelated individuals, may be a product of either **mutualism** or reciprocal **altruism** (see Table C.4).

Kin selection

William Hamilton's theory of **kin selection** is widely accepted as an explanation of cooperation among related individuals. Hamilton explained kin selection by noting that the greater the benefits of altruism (where the donor incurs the costs of action while the recipient benefits) between closely related individuals, the more likely cooperation will be worthwhile. This can also be explained in terms of an

individual's inclusive **fitness**, defined as the combined effects on fitness of the individual's altruistic actions towards its own offspring and other kin. If a behaviour is detrimental to the actor yet greatly benefits its kin, there is still a net increase in inclusive fitness. Close relatives are more likely to carry similar genetic propensities for altruism; by cooperating with close kin, an individual is promoting the transmission of these altruistic 'genes' - if not in itself then at least in others. Kin selection explains why individuals are more likely to assist close kin than distant relatives.

When **Charles Darwin** observed social insects in which certain castes are sterile (such as worker ants or worker honeybees), he was baffled by the possibility of individuals working cooperatively while forgoing their own reproduction. This type of social organization, known as **eusociality**,

P.138

describes cooperative care of a colony's young by both reproductive and sterile castes. In many insect colonies, this is possible because the sterile worker insects are what Hamilton termed 'supersisters'. Honeybees, for example, are haplodiploid, where fertilized eggs mature only as females. All workers are female, and are related to one another by a factor of $3/4$, a fraction that indicates the average proportion of one's own genes that are identical to the other's genes (**see also: Genetics of behaviour**). In sexually reproductive animals, including humans, a parent's offspring are related to the parent and to each other (if full siblings) by $1/2$. An eusocial worker is thus more closely related to her sisters than she could possibly be to her own offspring, were she able to reproduce. This may explain why a sterile honeybee is willing to defend her sisters and the colony's younger generations by stinging an intruder, an act that is always suicidal.

Other animals, such as birds and mammals, also show kinselected cooperation. Lions (*Panthera leo*) of the Serengeti in Africa live in prides, which typically consist of multiple adult males and females. Adult females breed synchronously, and spend much of their time together. A lioness will sometimes nurse young cubs that are not her own. She is much more likely to do so, however, when the cubs belong to close kin and the group's litter size is relatively small. In lions, it appears that communal nursing is highly influenced by the need of females to keep cubs together and protected (Pusey and Packer, 1994).

Florida scrub jays (*Aphelocoma coerulescens*) perform a particular form of cooperative breeding known as 'helping at the nest' that offers an important illustration of kin-selected behaviour. The Florida scrub jay is sexually monogamous and does not migrate. Helper birds assist more than 50% of monogamous pairs, and most helpers are previous offspring of the pairs they assist. Helpers often feed young (usually their siblings) and assist in defending the territory of the breeding pair (Woolfenden and Fitzpatrick, 1984). Predation is reduced due to the increased level of territory defence.

Scientists often study behaviour by attempting to determine how it benefits an individual's own fitness versus its inclusive fitness. Altruism lowers one's own fitness, but can be beneficial overall if the act increases the survivability of close relatives. Although cooperative breeding is detrimental to the helper's own breeding success at the time of cooperation, helping for a few years increases inclusive fitness because the cost of forgoing production of one's own offspring is outweighed by the benefits of helping to raise close kin. This behaviour can eventually lead to the creation of one's own territory and so positively affects one's own fitness. A young scrub jay that helps its parents increases the likelihood it will eventually take over their territory, or create another one nearby. After a helper disperses, the chances of forming one's own territory increase substantially. Cooperative breeding then both increases an individual's inclusive fitness and allows it to obtain valuable experience.

Mutualism and reciprocity

How an individual chooses a partner with whom to cooperate depends on two factors: (i) the proven effectiveness of partnering with a particular individual in cooperation; and (ii) the benefits received through their cooperative efforts. These return benefits may occur either immediately if partners share

the pay-off of their cooperation or - in case all the benefits go to one individual - after a time interval. The first case is known as mutualistic cooperation. The second is reciprocal altruism, or delayed reciprocity. For a review of the literature on cooperation among unrelated individuals, see Lee Dugatkin (1997).

A typical example of mutualism is the aforementioned one of African wild dogs chasing a gazelle, in which all hunters may benefit at the moment the ungulate is killed. A pack of carnivores that cooperates to bring down prey will receive one large reward distributable across all of the hunters. Another good example of mutualism, in this case between species, is that of the bluestreak cleaner wrasse (*Labroides dimidiatus*), also known as the cleaner fish. Usually found on coral reefs in the Indo-Pacific, cleaner fish establish what are known as 'cleaning stations', usually in a cave or under a rock formation, and perform a particular 'dance' to attract larger fish. The larger fish then line up, waiting to be cleaned. The cleaner fish eat ectoparasites off the host's body, often entering the mouth and gill regions to complete the job. Although the larger fish may have the opportunity to eat these cleaner fish, they do not. The benefits of having ectoparasites removed now and on future occasions apparently outweigh the benefits of a quick meal. In exchange for reducing the parasitic load of a larger fish, the cleaners receive a nutritional benefit.

Reciprocal altruism is more complex than mutualism in that it requires the foregoing of benefits, at least for a brief while. In 'The evolution of reciprocal altruism', Robert Trivers (1971) postulated that such behaviour might evolve if one individual's altruism (defined as costly behaviour that benefits others) towards another is being repaid after a time interval by the latter's altruism towards the former. If for both exchanged acts the recipient's benefits (B) exceed the performer's costs (C), and both acts are equal in this regard, both parties will gain $B - C$.

Reciprocity thus boils down to 'I'll scratch your back, if you'll scratch mine'. How many animals show such tit for tat? In their quest for evidence of reciprocity, scientists initially focused on group-wide distributions of behaviour. If individual A often aids B, and B does the same for A, and a whole group follows this pattern, the result will be a positive correlation between given and received support. Monkeys and apes, for example, form coalitions within their groups, such as when two or more individuals gang up on a third. Coalitions show healthy correlations indicative of reciprocity. But these correlations do not tell us exactly how benefits find their way back to the original altruist. Do animals keep score? This is hard to imagine for small-brained animals. Possibly they just divide the world into 'buddies', which they prefer, and 'nonbuddies', about which they care little. If such attitudes are mutual, relationships will be either mutually positive or mutually negative. Such symmetries can account for the simple reciprocity reported for fish, vampire bats, dolphins and many monkeys.

A widely cited example of reciprocal altruism involves blood sharing in vampire bats (*Desmodus rotundus*; Wilkinson, 1984). Vampire bat roosts consist of large groups of females that travel to collect blood meals. Individuals that have fed recently will return to the roost and sometimes regurgitate food to conspecifics that had been less lucky and remained unfed on

P.139

that night. These regurgitations may save their lives: a vampire bat will starve to death if it does not receive a blood meal within approximately 2 days. In addition, vampire bats can distinguish between individuals within their colony, and have special partners with which most exchanges take place. Wilkinson's studies indicate that relatedness and previous exchanges play an integral role in the blood sharing among vampire bats, on a level that may be as simple as 'buddy' versus 'non-buddy' distinction.

Reciprocity becomes more complex if there is a contingency between given and received favours. If the behaviour of A towards B depends on what B did earlier to A, we are getting close to benefit exchanges based on **memory**. Two examples will be given of experiments in this domain: (i) cooperation between

brown capuchin monkeys (*Cebus apella*), in which food is shared with a helper; and (ii) food-for-grooming exchanges among chimpanzees.

Captive capuchin monkeys can be positioned such that they can see each other but are separated by a mesh partition. In front of each monkey is a pull bar attached to a tray with two bowls (see Fig. C.12). Two test conditions can be compared, both requiring different amounts of 'pull' to bring the tray towards the monkeys. In the solo effort task, only one monkey has access to the pull bar and the bowl with food. The strength of one monkey is enough to pull in the tray. In the cooperation task, the tray is counterweighted such that the strength of both monkeys is required to pull in the tray. Both pull bars have to be utilized, but only one of the bowls has food.

In previous studies, it has been shown that these monkeys follow a pattern known as facilitated taking, where a food possessor will approach the mesh divider, dropping crumbs or whole pieces of food so that the partner can reach through the mesh and collect the food. This is an active form of sharing because the food possessor could just as easily stay away from the divider and hoard the food. When the two monkeys are involved in a cooperative pulling task, the food possessor is much more likely to participate in facilitated taking with the helper than in the solo effort trials, when there is no cooperation. In addition, the results indicate that the helper pulls more often in the cooperation trials when the preceding trial has been successful than if it had failed.

Fig. C.12. The test chamber used for the cooperative pulling task in capuchin monkeys (drawing by S. Brosnan).

It appears that capuchin monkeys are able to recognize and reward other individuals that have helped them obtain food in the immediate past by allowing them more access to the rewards thus obtained. This may be a result of attitudinal reciprocity based on an 'If you're nice, I'll be nice' principle. The reason to talk of attitudinal reciprocity is that the interval between exchanges is very short, and it is unclear how much memory or record keeping is required to attain the payment-for-labour observed. When the interval between exchanged acts becomes longer reciprocity becomes more complex, as demonstrated in the chimpanzee. Food-for-grooming exchanges in chimpanzees are thus far the only well-documented case of so-called 'calculated reciprocity', defined by mental scorekeeping among individuals for given and received favours. Although chimpanzees have distinct social hierarchies where alpha males get the

majority of the reproductive opportunities, food sharing is often peaceful and appears to be independent of social rank (see Fig. C.13).

In a study conducted by de Waal (1997), a captive group of chimpanzees was fed browse (i.e. large bundles of branches with leaves) twice a week during the spring and summer over a period of 3 years. Grooming behaviour was recorded for a period of 2 h prior to each feeding trial. Subsequent sharing during the food trials was then compared with data on grooming. This study indicated that chimpanzees were more likely to allow others to take food from them (by taking it from their hand or mouth) when the other had donated grooming services. In addition, chimpanzees that solicited food from individuals they had not groomed prior to being fed were more likely to be met with resistance and aggressive protests than individuals that had groomed the food possessor prior to the feeding. This indicates that chimpanzees not only remember having been groomed by a particular individual, but reciprocate the grooming with another positive behaviour, food sharing. This is in fact the only well-documented case of a memory-based contingency between given and received services.

Fig. C.13. Chimpanzees sharing food.

P.140

Charles Darwin wrote 'Nothing is easier than to admit in words the truth of the universal struggle for life', and argued that this struggle would be quite evident between individuals competing for the same resources. Ironically, cooperation evolved precisely because it helped animals to outcompete less cooperative variants. In both intraspecific cooperation (as in chimpanzees and monkeys) and interspecific

cooperation (between the cleaner fish and their 'client' fish), the benefits of working together outweigh those of working alone.

Coping

Individuals must continually cope with a certain level of **stress** imposed on them from their external environment. Aversive stimuli such as a change in temperature, light level, disease, restriction of movement and lack of food all impose a level of stress and, unless avoided or dealt with, may result in reduced **fitness**. The amount of stress that they place on an individual depends on their nature, intensity, duration and degree of novelty. Coping is the term given to the mechanism by which an individual deals with these stressors. Changes in physiology and behaviour are made by the individual and, if effective, result in a return to an optimal state, in a process referred to as **homeostasis**. The extent to which an individual can eliminate or negate the stress inflicted on it by making these changes reflects the extent to which it is coping.

Responses may include physiological changes in the body - for example, production of antibodies, an increase in heart rate or behavioural reactions such as vocalization or movement. To illustrate, if the air temperature within an animal housing system falls, thermoreceptors on the surface of an individual animal's skin will detect this change. The **brain** may stimulate the contraction of pilo-erector muscles, raising hairs on the surface of the skin, which helps to reduce heat loss in response; but, if the body temperature falls below a **critical temperature** threshold level, greater metabolic effort may be required to maintain the body temperature. The individual may also respond behaviourally and move to a warmer part of the housing system. If these responses are successful, the individual will soon return to optimal temperature and its fitness will not be compromised.

Levels of stress and coping

Individuals cope with low-level stress constantly, and behavioural responses may be unnecessary or minimal as they are generally, energetically speaking, quite expensive. More aversive stimuli may inflict a higher level of stress on the animal and a behavioural response may be elicited, for example by moving to a warmer part of their living quarters (level I). This level of stress is still low and, if the animal has the appropriate behavioural or physiological mechanism, it can cope with it relatively easily. More intense, prolonged, novel or noxious stimuli may impose a higher level of stress on the animal and it may have greater difficulty coping (level II). A greater intensity of response may be required, or a novel response that would not be utilized at lower levels - for example, shivering or huddling behaviour. The animal may be able to cope indefinitely with this level of stress but it is likely that its welfare will be compromised in time. Particularly noxious or prolonged stressors may exceed the animal's capacity to cope (level III). Fitness, as in potential for **reproduction** and survival, is compromised at this level and may even be affected at level II. Their tolerance of this level of stress is limited and, if it is not removed, the animal may collapse and die, for example from hypothermia.

Stimuli may have a compound effect in that a number of noxious stimuli may produce a level of stress greater than the sum of their parts. For example, an animal may be coping with a low level of stress (I), but the addition of other mild or more severe stressors raises the level to such an extent that the animal struggles (II) or even fails to cope (III), unless it is able to change to a different coping method (see Table C.5).

Coping behaviour is that behaviour which is performed with the aim of reducing the effects of an aversive stimulus on the fitness of an individual. The detection of noxious stimuli and the appropriate behavioural response to these is therefore an adaptation. Coping behaviour may involve ways of removing, reducing or avoiding the stimulus. In the example above, moving to a warmer part of their environment is an example of coping behaviour.

Consistent forms of coping behaviour are described as coping strategies. It has been suggested that the most common ones are 'escape', 'remove', 'search' and 'wait' (Wechsler, 1995). Avoidance of a noxious stimulus by physically escaping from it is often the first coping strategy used by an animal. Removal of the stimulus, for example, by attacking it, may be utilized, particularly if escape is not possible. 'Search' may be an effective strategy for some situations, including coping with hunger. 'Waiting' for the situation to change may be the strategy utilized when these other strategies are not possible or successful, and may explain apparently apathetic behaviour seen in caged animals (Wechsler, 1995).

Not all individuals or species will cope with an aversive situation in the same way. The kind of strategy an animal tends to utilize may depend on its individual tendency or 'coping style'. The idea of coping styles came from the observation that individuals may show consistent behavioural and physiological tendencies in a variety of environmental situations. These tendencies have been characterized on an ordinal scale from 'reactive' to 'proactive' or from 'passive' to 'active'. For example, Koolhaus and Bohus (1989) found that mice that were aggressive to an unfamiliar mouse in their cage tended to cope with the introduction of an electric shock prod into their cage by burying it with bedding material. They suggested that these mice had 'active' coping styles. Less

P.141

aggressive mice tended to avoid the prod, which was defined as a more 'passive' coping style. In these situations, however, both styles were equally effective at avoiding the aversive stimulus (being shocked). The extent to which the concepts of active and passive coping styles can be applied to different species is a matter of some debate.

Table C.5. Levels of stress and coping ability (adapted from Broom and Johnson, 1993).

Stress level	Coping ability	Response	Tolerance	Fitness
III	Not coping	No response available, collapse	Not tolerable, lethal if continues	Reduced
II	Difficult	Large or extra responses needed	Indefinite, but barely tolerable	Reduced
I	Easy	Large or extra responses needed	Indefinite	No effect
Normal	Easy	Small homeostatic changes	Indefinite	No effect

The **welfare** status of an individual or group of animals can be defined in relation to how well they are coping with the stresses imposed on them by their environment. For example, within intensive housing systems animals may have difficulty coping for a number of reasons and, by inference, their welfare status may be compromised. The **stressors** may be too numerous or too great to allow for effective coping, the animal may not have appropriate coping strategies in its behavioural repertoire because its species did not evolve in this environment and/or the animal may be prevented from utilizing its coping strategies effectively because of the restricted environment. For example, 'escape' or 'remove' may not be possible, and 'wait' may be not be effective in the long term since the situation may not change. It has been suggested that some **abnormal** behaviour patterns might be the result of unsuccessful coping strategies (Wechsler, 1995).

Coprophagy (coprophagia)

Coprophagia describes the ingestion of faeces. The faeces consumed by a coprophagic animal may be its own (e.g. rabbits consume their own faecal pellets, which then undergo a second wave of digestion), those of another species (e.g. dogs may consume **cat** faeces) or a **conspecific** (e.g. foals consume faeces of adult **horses**, especially from their dam).

Foals are the most closely studied of these groups. Often seen pawing at faecal material, foals may use coprophagia as one method of learning about the gustatory and olfactory features of plants consumed by the dam. The significance of this activity in learning is supported by the coincidental decline in the foal's interactions with toxic plant species during the transient phase of coprophagia. There may be an additional purpose, such as the acquisition of intestinal microbes and possibly deoxycholic acid, thought to play a role in the deposition of myelin. For these putative reasons, hand-reared foals should be given the opportunity to perform coprophagy, a practice that is highly unlikely to expose the foal to viable forms of endoparasites. Although coprophagia is rarely seen in adults, fibre-restricted rations, **frustration** (which probably results from the same deficit) and underfeeding in general can cause its appearance in adult horses.

When encountered in dogs, coprophagia is considered unwelcome by many owners. The reasons for its emergence are poorly understood, and therapies are often confined to reviewing the formulation of the diet, extinguishing attention seeking and using taste deterrents on target faeces (**see: Aversion**). The prevalence of this response among kennelled dogs suggests that environmental enrichment should be a part of more comprehensive therapeutic responses.

Rabbit accommodation should always include some solid flooring, because cages with wire floors compromise the occupant's ability to consume faeces, otherwise coprophagia, part of the animal's natural digestive cycle, may be jeopardized.

Core area

The core area (also called centre of activity) is an intensively used area within the **home range**. Plotting an animal's locations on a map, it would be the place or places with a dense cluster of points. Alternately, viewing the data as bars of various heights representing frequency of use (the **utilization distribution**, UD), the core area would be the cluster of tall bars.

Sometimes, the core is defined as the smallest region encompassing 50% of the UD (the 50% isopleth). However, this value is arbitrary and often not particularly fitting for real-life situations: for example,

suppose only 30% of the locations were clustered in a small area and the other 70% were rather evenly dispersed. Methods based on the actual dispersion of the data for each individual animal are more consistent with the concept of core area. However, no universally adopted method has emerged.

All methods assume that the UD is accurately measured. Problems arise if the sampling is insufficient (clusters of locations reflect periods when the data happened to be collected) or biased (certain areas appear to be heavily used only because the observer could more easily find the animal there).

Core areas may change seasonally or over a shorter time scale, with changing food, weather or biology of the animals

P.142

(breeding, birthing, rearing of young, etc.). Moreover, multiple disjunct core areas may exist, corresponding with favoured sleeping, feeding or birthing sites (dens), or a portion of the home range not used by conspecifics.

It is generally presumed that core areas represent preferred habitat within the home range. As such, some conservation plans for threatened species call for the protection of core areas. This approach has drawn criticism because: (i) other large parts of home ranges may be just as important, but with less concentrated use (e.g. an expansive foraging area versus a core refuge area); and (ii) there is no general agreement on how to define core areas.

Corticosteroids

Corticosteroids are steroid hormones produced by the cortex of the adrenal gland. These include: (i) the mineralocorticoids (e.g. aldosterone), which are vital for the regulation of sodium and potassium levels in the body; (ii) the precursors to the sex steroids (e.g. androgens and oestrogens), which contribute to establishing and maintaining secondary sexual characteristics; and (iii) the glucocorticoids (e.g. cortisol or corticosterone), which are critical in carbohydrate and protein metabolism. Corticosteroids exert their effects in the body by determining the nature and rate of gene transcription in target cells.

Mineralocorticoids

Mineralocorticoids, as their name suggests, have a role in mineral metabolism. Aldosterone is the principal mineralocorticoid involved in this process, and this hormone is involved predominantly in regulating the exchange of sodium and potassium ions in the distal tubule of the kidney. The resulting physiological effects are an increased resorption of sodium, increased resorption of water and increased renal excretion of potassium.

Aldosterone exerts its effects by stimulating transcription of the gene encoding sodium-potassium ATPase, leading to an increased expression of sodium-potassium pumps in the basolateral membranes of tubular epithelial cells. It also acts to stimulate expression of sodium channels in the tubular lumen, facilitating uptake of sodium in this region. The active resorption of sodium facilitates the passive flow of potassium into the tubular **urine**. The flow of potassium across the membrane is dependent on the rate of sodium delivery and the distal nephron flow; however, aldosterone allows potassium to flow across the membrane (in a restricted quantity) even when sodium levels are low. Aldosterone also exerts its effects on the colon, where it stimulates sodium resorption from this area, thereby enhancing potassium excretion in the faeces. It also acts on the sweat glands and salivary glands, using a similar mechanism to that described above.

Secretion of excess aldosterone also results in increased blood pressure. This is due, in part, to the retention of sodium, expansion of the extracellular fluid and an increase in cardiac output. In addition, the increase in sodium and water content of the arteriolar cells may increase, thereby causing the arteriolar lumen to narrow and increase resistance in the artery.

The three most significant factors affecting the regulation of aldosterone are: (i) the concentrations of potassium ions in the extracellular fluid (increased levels of potassium stimulate the production of aldosterone); (ii) the concentration of sodium ions in the extracellular fluid (decreased levels of sodium stimulate aldosterone production); and (iii) angiotensin II (a decrease in renal blood flow results in activation of the renin-angiotensin system and a concomitant secretion of aldosterone).

Precursors to the sex steroids

The precursors to the sex steroids (i.e. DHEA-S, DHEA and androstenedione) are relatively weak androgens secreted from the adrenal cortex. They are converted into the more potent androgen, **testosterone**, which acts to influence the formation and maintenance of secondary characteristics (e.g. pubic and axillary hair in humans) in both sexes. Testosterone has more influence on male than female sexual characteristics, as the production of this hormone from the testis in the male far exceeds that of the adrenal gland, rendering cortical secretion physiologically unimportant in this sex.

Glucocorticoids

The glucocorticoids are hormones involved in energy production. Secretion of cortisol (in primates, dogs, cats and most ungulates) or corticosterone (in rodents and birds) induces breakdown of protein to release glucose into the bloodstream, where it is used to provide energy to the organism. Cortisol is also involved in fat metabolism, muscle, renal and immune system functioning, maintenance of the skeleton and modulation of the activity of the **central nervous system**.

When an animal is exposed to a novel or disturbing situation it experiences **stress** to varying degrees. Any event, whether it is physiological or psychological, that disturbs the organism's **homeostasis** is able to cause a stress response and secretion of corticosteroids from the adrenal cortex. The difference between adaptational and maladaptational physiological responses is the duration and persistence of hormone secretion.

When exposed to acute conditions of stress, an animal prepares for an immediate response, typically in the form of the fight and flight response, and the **sympathetic nervous system** and **hypothalamic-pituitary-adrenal (HPA) axis** are activated. Activation of the HPA system causes corticotropin-releasing hormone (CRH) to be released from

P.143

the **hypothalamus**, which appears to mediate a variety of anxiogenic and depressogenic behavioural effects associated with increased arousal, alertness and other changes characteristic of heightened alertness to the environment. CRH acts on the anterior lobe of the **pituitary gland** where, together with **vasopressin**, it stimulates the secretion of adrenocorticotrophic hormone (**ACTH**). ACTH, in turn, exerts its effects at the cortex of the adrenal gland, causing the synthesis and secretion of glucocorticoids. Regulation of the activity of the **HPA axis** is performed, in part, by the glucocorticoids, which exert negative feedback effects at both the hypothalamus and pituitary gland to regulate the production of ACTH.

The receptors for cortisol exist in two forms, classified by the specificity of different steroids and neuroanatomical distribution: (i) the mineralocorticoid or type I receptors (MR), which bind both corticosterone and cortisol with high affinity; and (ii) the glucocorticoid or type II receptors (GR), which have approximately one-tenth the affinity of MRs but bind the glucocorticoid analogue dexamethasone.

The GR is most abundant in regions associated with the behavioural stress response (e.g. the hippocampus and hypothalamic paraventricular nucleus). MRs are mainly restricted to limbic brain regions, and the density is particularly high in the neurones of the hippocampus. MRs are thought to regulate the basal level of activity of the HPA system. The majority of the MRs are occupied when the animal is at rest and the corticosteroid levels are low; however, when the animal becomes stressed, and corticosteroid levels increase, the GRs become occupied. The relative binding of the hormone with either the GRs or MRs, therefore, seems to be an important determinant of limbic activity. This activation is influenced by factors such as affinity of the receptors, the concentration of corticosterone circulating in the bloodstream and regulation of receptor synthesis.

The predominant effect of cortisol is to facilitate the conversion of protein to glycogen. It does this by accelerating protein degradation and inhibiting protein synthesis, thereby augmenting mobilization of muscle protein for gluconeogenesis. The energy released by gluconeogenesis is subsequently utilized to facilitate behavioural activity as the organism responds to a stressful situation.

Even when an animal is 'unstressed' (i.e. undisturbed physically or psychologically), a daily rhythm in cortisol production can be observed in both diurnal and nocturnal animals. Maximal concentrations are measured concomitant with the onset of locomotor activity, prior to or at awakening. This occurs, therefore, in the morning in diurnal species and in the evening in nocturnal species. In diurnal species the levels of cortisol decrease gradually throughout the day to become a minimum just before the animal retires for the night. In nocturnal species the levels are maximal in the evening as the animal wakes. It is thought that high cortisol levels upon waking may serve to mobilize energy stores in preparation for activity.

When an animal experiences acute stress, e.g. by being placed in social isolation or by being exposed to certain novel stimuli, an unfamiliar conspecific or a predator or particular drugs (e.g. ether stress), it exhibits the 'fight or flight' response. Animals exhibiting this reaction will show an increase in locomotory and active behaviour, will orientate themselves towards the offending stimulus and will vocalize at an increased rate. It has been suggested that the rate, intensity and type of **vocalizations** that an animal emits when exposed to a disturbing situation can give an indication of the stress levels, and hence the psychological state of the animal at that time. The increase in these behaviours has, in some cases, been shown to correlate with increasing cortisol levels in response to various types of arousing stimuli. However, despite providing an indication of the psychological state of the animal, behavioural parameters

alone do not always give a conclusive reflection of the amount of stress the animal is experiencing. Therefore, when aiming to assess the psychological state of an animal, it is useful to examine both behavioural and physiological parameters together to reach a more accurate conclusion.

The stress response can be induced in animals by exposing them to potentially disturbing situations. One traditional method of inducing the stress reaction in an animal is to expose it to **social stress**, which, in many cases, can be achieved by placing the animal in a group of unsuitable conspecifics. The degree of HPA axis activation (and hence the magnitude of glucocorticoid secretion) in response to social stress, is determined by two principal factors: (i) social context, defined by the position in the hierarchy, gender and the presence of conspecifics; and (ii) individuality, determined especially by early environmental experiences (although later conditioning can also affect this response) and genetic determinants, including parent-infant bonding. The social context and individuality may account, in part, for the varying results found when testing the same species under the same conditions.

Other factors which may affect HPA axis activity are group stability, size and composition (whether or not a **social group** is stable or whether there is competition for dominance). The magnitude of the adrenocortical response also varies between species, and indeed between breeds in domestic animals. This enhances the need for careful control of genetic diversity and use of large sample sizes when assessing corticosteroid response to a treatment.

Situations in which an animal experiences **pain** have been shown to be associated with increased glucocorticoid secretion. Studies have shown an increase in cortisol levels in response to procedures such as surgery, tail docking, **castration** and **mulesing** (the removal of skin folds in the sheep to prevent fly strike). In many of these studies the severity of the procedure correlates positively with the magnitude of the adrenocortical response. Adrenal activation in response to situations that are predictably painful can be reduced by the use of analgesics. However, it has also been shown that the adrenocortical response can be initiated even when anaesthetic is used, suggesting that the tissue damage itself, even if not perceived as painful by the CNS, results in corticosteroid secretion.

Chronic stress is characterized by a long-term elevation in glucocorticoid secretion. This results in a down-regulation of GR and MR mRNA and ligand binding in the hippocampus in response to prolonged receptor activation. Chronic elevation of glucocorticoids indicates a maladaptational adjustment to environmental conditions.

Chronic stress has also been associated with degenerative changes in the **brains** of primates and rodents, mediated in

P.144

part by the GRs. A sustained elevation of glucocorticoids results in neurotoxic effects and cell death, which potentially contributes to a loss of negative feedback control of the HPA axis. Chronic stress has also been shown to result in persistent inhibitions of granule cell production and structural changes in the hippocampus. Excess glucocorticoids interfere with nerve cell function in the hippocampus, interrupting processes in the synapses that are thought to be involved with memory and learning. They have also been shown to interfere with the uptake of glucose by hippocampal nerve cells, making them vulnerable to other insults, such as lack of oxygen occurring during strokes or epileptic seizures, which may eventually lead to the death of these neurones. If the feedback mechanisms fail various pathophysiological consequences can arise, and hypersecretion of glucocorticoids at a chronically elevated concentration can have deleterious effects on the **immune system**, metabolism, reproduction, tissue repair and neurologic status.

When animals are exposed to chronic stress - for example, when they are housed in unnatural and confined spaces for long time periods - they may exhibit an alternative stress-induced reaction. Under conditions such as this, the fight or flight response can be gradually replaced with abnormal behaviour patterns such as stereotypic behaviour and apathetic behaviour. **Stereotypies** are repeated actions of a

singular behaviour or pattern of behaviours that have no functional purpose and, in fact, may often be maladaptive. Some examples of stereotypies are the rocking of a primate reared in isolation (which possibly develops as a substitute for the proprioceptive and kinaesthetic stimulation that it would usually receive from its mother), cage circling of a confined and unstimulated marmoset or the pacing of a confined and unstimulated cat. Another less obvious stereotypy is the facial grooming of mice when they are exposed to a stressful or novel environment. In this case the behaviour is not affected by lesions that block sensory input from the facial area, suggesting that the performance of this behaviour is indicating unease, rather than a need to groom the facial area.

A number of techniques have been developed to measure cortisol levels. One commonly used method is to assay the cortisol levels in blood plasma. Assessment of cortisol levels using this method is useful to obtain an accurate indication of the levels of cortisol in the blood at any chosen point in time. However, care should be taken when using this technique, as the capture and restraint required during collection of the sample for assay, together with the adversiveness of venipuncture, may itself cause stress to the animal and confound the results obtained. Urinary and faecal cortisol analyses have also been used to examine daily fluctuations in cortisol and can be useful in examining cortisol levels in free-ranging animals or when samples are not required to be obtained at a high frequency. Saliva sampling is a useful alternative to these methods. It is non-invasive, is less stressful than collecting samples using blood-sampling techniques and can be used at frequent intervals in a majority of captive settings. It does, however, require that subjects are trained willingly to provide saliva samples in advance of the period of experimentation, to avoid stress being caused due to the procedure of sample collection. Cortisol concentrations are assessed using radioimmunoassay techniques.

Corticotropin-releasing hormone (CRH)

Corticotropin-releasing hormone is a peptide produced in the paraventricular nucleus of the **hypothalamus**, from where it is carried via the portal circulatory system to the anterior **pituitary gland**; it stimulates the production of adrenocorticotrophic hormone (ACTH) and thus an increase in **corticosteroid** levels. CRH production is stimulated by the **cytokine**, **interleukin-1 β** , which also plays an indirect role in sensitizing the **brain** to **pain** associated with the inflammatory response, although CRH itself may interact with receptors that stimulate positive effects. CRH is also produced in some peripheral tissues, including T-lymphocytes, but most notably the placenta, and an increase in CRH production towards the end of pregnancy results in the fetal surge in corticosteroid production that triggers parturition.

Cost-benefit analysis

In utilitarian ethics, the consequences of any action are an important aspect of deciding what actions are right and wrong. In animal research, the cost-benefit (CB) approach is embodied in the UK 1986 Animals (Scientific Procedures) Act, and the Secretary of State for the Home Office is charged with weighing the likely adverse effects on the animals involved against the benefit (to humans, other animals or the environment) likely to accrue from the programme of work outlined in the project licence. In its simplest form, if the likely benefits outweigh the predicted **harms**, then an action can be said to have some justification. However, in practice, the CB analysis comes with a range of other questions. Is the objective

worth pursuing? Are *avoidable harms* going to occur? How good are the predictions of the harms? Is there proportionality, that is are the harms commensurate with the anticipated benefits?

It is likely that higher levels of animal **suffering** will be permitted when the anticipated benefits are high (e.g. saving human lives, promoting quality of life for humans, developing an AIDS vaccine) than in a project where the benefits are less important, e.g. one that might make farm animals grow faster, or that results in meat being produced more cheaply or advancement in knowledge. The CB approach can be used to evaluate any area of animal use. For example, some consumers will only purchase free-range eggs as opposed to eggs from hens kept in battery cages for, in their view, the costs (for humans) of eating free-range eggs are outweighed by the perceived benefit to the birds in terms of their **welfare**. Using a similar CB argument, other persons will not eat eggs at all, because the harms imposed on hens kept in cages or free range are so great that they are not outweighed by the pleasure gained by eating eggs.

Several problems arise with this approach in research. First, the anticipated benefits may not occur, whereas the harms done to animals are more accurately predictable, e.g. postoperative pain. So the benefits have to be realistic. Some benefits, even though not achieved, may still provide useful information, resulting in increased knowledge. Secondly, in other areas of animal use, the benefits may be 'base' pleasures

P.145

such as humans exploiting natural animal instincts as in dog fighting, or **baiting** of wild animals. Thirdly, costs and benefits are often in different 'currencies' for members of different species. Although it may be possible to propose a hierarchy of acceptability of benefits, with an animal experiencing cost above other animals of the same species who are above animals of a different species. So the type of pleasure or benefit has also to be considered. CB arguments can be used to justify, or otherwise, a range of issues such as the torture of human subjects, infringing the liberty of some for the greater good of the many.

Council of Europe

The Council of Europe, established in 1949 by the Treaty of Rome, is based in Strasbourg, France. Following World War II, it was an attempt to reconcile and establish cooperation across Europe. It should not be confused with the European Community, and does not make laws, but encourages a wider membership to abide by conventions, protocols and treaties which set out principles on issues of common interest. Its main areas are democracy, rule of law, human rights and freedoms and, more recently, terrorism and crime. Its strength is in bringing together members for debate but, with little real power, could be seen as no more than a discussion forum. It is unelected, therefore potentially undemocratic, and the conventions are not legally binding, with nations able to choose whether to sign up to them, with no direct consequence should they not do so.

Sample European Conventions of relevance to animal behaviour and welfare include: (i) Convention for the Conservation of European Wildlife and natural Habitats (1974); (ii) Convention for the Protection of Animals during International Transport (1968, 1979); (iii) Convention for the Protection of Animals kept for Farming Purposes (1976, 1992); (iv) Convention for the Protection of Animals for Slaughter (1979); (v) Convention for the Protection of Vertebrate Animals Used for Experimental and Other Scientific Purposes (1986); and (vi) Convention for the Protection of Pet Animals (1987).

(BG)

Counter-conditioning

Counter-conditioning, or response substitution, is a commonly used behavioural modification technique for the alleviation of behaviour problems in animals caused by inappropriate arousal to a given stimulus. The term literally means training an animal to do a behaviour that is counter to the one that a trainer wishes to eliminate, i.e. producing an incompatible response to a given stimulus that is expressed in preference to the undesired response. The technique is widely used in combination with systematic desensitization (**see: Desensitization - systematic**). By ensuring that the preferred behaviour is more rewarding, the animal learns to perform the new behaviour when exposed to the potentially problematic stimulus. There are two ways in which counter-conditioning is usually undertaken.

First, during exposure to the problem stimulus the animal can be presented with a stimulus that inherently arouses an alternative emotion (or respondent behaviour), which is counter to the emotion underlying the problem behaviour. For example, a toy may be produced to encourage playing or food to encourage eating when a thunderstorm starts; the responses elicited by these stimuli are incompatible with a fear response. If the animal begins to show signs of anxiety the intensity of the stimulus needs to be reduced before the counter-stimulus (food, toy, etc.) is withdrawn - for this reason recordings of the aversive stimulus may be used during the training process. Eventually the animal should learn that the problem stimulus is now a predictor of a positively reinforced (rather than aversive) event. As a result the problem behaviour is eliminated - this version of the process is also known as respondent counter-conditioning, or classical counter-conditioning.

Alternatively, the animal may be trained with reinforcers to undertake a specific action that is incompatible with the problem behaviour (e.g. a 'sit-stay'). This operant behaviour may initially be trained to a command or signal, which is then paired with the problem stimulus. It is obviously essential that the cue used to elicit the obedience response is more likely to be responded to than the aversive stimulus. This process is called operant counter-conditioning. Once the problem stimulus reliably predicts the counter stimulus and elicits an acceptable response, it is usually possible to fade out the cue if the behaviour is appropriately reinforced.

Courtship behaviour

Courtship behaviour precedes and accompanies the sexual union of male and female animals. The form, flamboyance and length of courtship vary considerably from species to species. Some species reproduce with very little interaction, while others have very complex courtship patterns that can last hours or even days. These often involve stereotypic movements and the display of bright colours, striking patterns and the production of loud **vocalizations**. The function of courtship behaviour is to create the circumstances in which successful mating is possible. Within this framework there are a number of aspects that should be considered.

The first step leading to a successful mating is locating a **conspecific** member of the opposite sex. For some species this is not an issue because males and females live together in permanent mixed-sex **groups**. However for solitary and sexually segregated species, attraction of a conspecific individual of the opposite sex, sometimes over a considerable distance, is an integral part of courtship behaviour.

The **signals** used by animals to attract mating partners are known as mate attractant signals. To be effective, mate attractant signals must provide information about the species, sex, receptivity and location of the signaller. In many species, only one sex gives the signal and only when it is receptive. This means that the signal need only be species specific and locatable, since sex and receptivity are implied by presence of the signal itself.

Different species use different kinds of signals to attract mates. Visual, auditory and chemical (odourant) signals are the

P.146

most common, and the modality used depends to a large extent on the habitat in which the species lives and the senses that have evolved in association with other aspects of its life. For example, birds have a keen sense of sight and hearing but a relatively poor sense of smell, and so they most commonly attract their mates using visual signals, like brightly coloured feathers or vocal signals, like songs. Insects and mammals, on the other hand, have a well-developed sense of smell used to detect food and so they commonly use **pheromones** to attract mates. Habitat type also influences the kind of signal used. Birds that live in forests where visibility is restricted often use songs or other vocal signals to attract mates, while those that live in more open habitats mostly use visual displays. A good example of such a display is the tumbling flight used by lapwings and woodcocks to attract females over considerable distances.

The type of signal used to attract mates is also influenced by the sex of the signalling partner. Most commonly it is the males that produce mate attractant signals and the modality used is often auditory or visual. For example, in many birds, lizards, newts, fish, fiddler crabs and mammals, it is the males that are brightly coloured, that develop enlarged body structures and that perform elaborate displays. Females are seldom as brightly coloured as males and almost never produce structures or engage in elaborate displays like males do. Similarly, in animals that use vocal mate attractant signals, the signalling sex is almost always the male. This is true for frogs, insects and some birds although, in some bird species, both males and females produce long-range vocal mate attractant signals. There are also a few species in which females produce vocal signals to attract mates. Female elephants emit ultra-low-frequency sounds to attract males when they are in oestrus. Olfactory signals are sometimes used by males to attract females (e.g. some species of beetles), but are most commonly used by females. This is true of many species of mammals, snakes, spiders and moths.

Mate attractant signals must travel over long distances and be easy for the receiver to locate. Visual, vocal and olfactory signals are most effective for transmission over a distance, but are also used during close-range interactions between potential mating partners. Close-range auditory and visual signals are often reduced in amplitude and intensity but have a higher duty cycle ('on' time relative to 'off' time). For example, male frogs produce calls at a much faster rate when a female is close by. Chemical signals used at close range are low-volatility compounds (evaporate less easily than those used for long-range signals) and are detected by contact receptors (e.g. the antennae of insects and the vomeronasal organ of reptiles and mammals). Electric signals, used by some species of fish, are well suited to short-range exchanges since they only travel over distances of less than 1 m, and tactile signals are only used when potential mates are in close contact with one another.

All signals that form part of courtship behaviour, whether they are used for attracting mates at a distance or during close-range encounters, contain information about species identity. In order for offspring to survive and go on to reproduce, it is crucially important that animals mate with members of their own species. Hybrid matings seldom produce any offspring at all, and those that are produced are unlikely to

produce viable offspring themselves. Courtship behaviour is a good way of facilitating mating between conspecific partners. For animals that use vocal signals, species identity can be encoded in either the temporal (time) or spectral (frequency) parameters of the signal, or both. For example, many frog species breed in large mixed-species assemblages. Males of each species attract conspecific females by producing unique, species-specific calls which differ from the calls of heterospecific males with respect to frequency, duration or repetition rate, or some combination of these parameters (see Fig. C.14). Females recognize calls by these differences and respond only to calls produced by conspecific males.

Species identity can also be encoded in visual signals. For example, firefly males produce flashes of light to which females are attracted. Different species of males produce signals that differ in the duration and temporal pattern of flashing. In fiddler crabs, males wave their major cheliped (an enlarged feeding claw) at passing females in an attempt to attract them to their burrows. Different species differ in the pattern of the waving display, as well as with respect to cheliped colour, shape and size (see Fig. C.15). All these may provide females with cues to species identity. For animals that use chemical signals, species identity is encoded in the chemical's size, shape and functional group. Pheromones generally consist of a carbon chain backbone with one or more double bonds in a specific configuration and one functional group at the primary end. In butterflies and moths, different species within a genus differ with respect to the functional group located on the end of the carbon chain.

Once a male and female are together, be it because they live in mixed-sex groups, through a chance encounter or by some form of mate attraction signal or behaviour, they must decide whether or not to mate. Often, one partner is more motivated to mate than the other. This is usually the male, because his energetic investment in gametes is lower than the female's. Males are therefore more likely to play an active role during courtship than females. Females are more cautious because they invest a significant amount of energy in the production of gametes, and so errors in species recognition or mate choice are more costly to females than males. Therefore, one important function of courtship behaviour is to induce sexual arousal in the partner, usually the female, which is less willing or motivated to mate. For example, in the smooth newt, males and females meet mainly by chance and initially the male is the active partner and the female is unresponsive. The courtship display by the male is therefore long and vigorous and is aimed at stimulating the female and eliciting a positive sexual response from her. Males posture to show off their bright coloration, and they also secrete a pheromone that the male wafts towards the female's snout by rapidly fanning his tail to create a current of water.

In addition to sexually stimulating the female, courtship behaviour functions to ensure copulation synchronization and/or synchronous gamete release. This often involves communication of receptive stages by both male and female. Copulation synchronization signals are usually visual or tactile and are common in many species of mammals and birds where fertilization is internal. In rodents, for example, the female adopts a stereotypical posture (**lordosis**), which signals the male to mount. Intromission by the male cannot be achieved if the female does not adopt this posture. In smooth newts

P.147

fertilization is internal, but the male does not have a penis. Instead, he releases a spermatophore, or sperm packet, on to the substrate, which the female then picks up with her cloaca (genital opening). After a complex courtship display by the male, the female signals her receptivity by touching the base of the male's tail. Once this occurs, he releases a spermatophore. Males will not deposit a spermatophore until the female has signalled that she will pick it up.

Fig. C. 14. Vocalizing male painted reed frog, *Hyperolius marmoratus*. Male frogs attract females from a distance using species-specific vocal signals. Male *H. marmoratus* use the same signal at close range, although they increase their rate of signal production (calling rate) as the female approaches.

Synchronous gamete release is very important for both sexes in fish and amphibians, where fertilization is external and eggs and sperm are released directly into water. In these animals, the male must release his sperm immediately after the female releases her eggs. In the three-spined stickleback, males defend territories containing a nest and display their territorial status through bright body coloration. When a receptive female (her receptivity is indicated by her swollen, egg-filled belly and a 'head up' display) enters the male's territory, he performs a 'zig-zag' dance, which involves alternate broadside and face-on postures. If the female responds to this display, the male swims towards his nest and the female follows. The male then stimulates the female with a series of prodding movements at the base of her tail, which induce her to release her eggs. The male then enters the nest and releases his sperm. Like sticklebacks, courtship in many other animals consists of a chain of interactions between the male and female. Neither partner will commence with the next movement in the sequence until the other partner has responded to the preceding movement. This ensures that both partners reach the stage of gamete release at the correct time.

Courtship signals not only ensure that mating occurs between males and females of the same species, but they also facilitate choice of mating partner from among *individuals* of the same species. The role of courtship signals in conspecific mate choice is especially apparent in those species that mate in groups. Where a number of males and females come together to mate (e.g. on mating grounds or 'leks'), there is great potential for rivalry between members of the same sex for access to members of the opposite sex.

The effect of this rivalry on courtship behaviour depends to a large extent on differences between males and females in reproductive potential. Female reproductive potential is much more limited than male. Because the production of eggs is a major energetic investment for females and because, in most species, females are the ones that care for the young, the number of eggs a female can produce in a lifetime is limited. Males, on the other hand, invest very little in each sperm and in many species play little or no role in the care of the young. The number of offspring a male can produce over a given period of time is therefore potentially much higher than a female.

Fig. C.15. *Uca vocans* fiddler crabs, male and female. The male attempts to coerce the female into his burrow using his rear ambulatory legs, in order to mate with her.

This difference in reproductive potential leads to the evolution of different reproductive tactics. To ensure the survival of their limited eggs, females need to ensure that they mate with males of the highest quality. This leads females to be choosy about the males they mate with, selecting and copulating with those males that are likely to offer them benefits that will maximize their limited reproductive potential. Males, on the other hand, will attempt to maximize their reproductive potential by mating with as many females as possible. Among animals that live in groups, this leads to fierce competition among males for access to females. Competition can take the form of intense fighting and aggression between rival males and/or the evolution of elaborate sexual displays, which not only attract the attention of females, but do so more effectively than the displays of other males.

There is now ample evidence in the literature that females of many species do not mate randomly, but selectively mate with males whose displays generate the strongest stimuli (e.g. are the most colourful, loudest, largest or most complex). A number of hypotheses have been proposed to explain female choice

of mating partners. One hypothesis (the 'good genes' model) suggests that females choose males that show particular displays/traits because they are costly and therefore provide

P.148

females with reliable cues of male genetic 'quality', which is inherited by the female's offspring. According to this hypothesis, only the highest-quality males are able to support the cost of producing extreme forms of the display (e.g. longest tails, brightest colours, loudest calls). Low-quality males either pay a higher survivorship cost compared with high-quality males for a given amount of energetic investment in the display/trait (for example, take large antlers in deer: low-quality males are unable to support the cost of growing large antlers and are more likely to die than are high-quality males) or they produce an inferior display (e.g. in some birds low-quality males produce smaller, less ornate feathers than do high-quality males, or their feathers are in worse condition).

Traits used by females to assess male genetic quality are therefore known as indicator traits. An example of an indicator trait is the red plumage seen in many bird and fish species. The size and intensity of red patches are often indicative of the levels of carotenoid pigments in feathers and scales. Carotenoid levels are often associated with immunological competency; sick males often exhibit a reduction in red coloration compared with healthy males, and only males with good immune system function (and hence disease resistance) can invest in intense colour production and remain viable.

A second hypothesis is that some male signals do not indicate genetic quality but, instead, provide females with information about how males can directly affect the survival of offspring. For example, a high calling rate by some male birds may indicate to the female that he can defend a high-quality nest site, and this may directly affect the survival of the female's chicks.

A third hypothesis is that some male displays do not provide females with any benefits at all (either genetic or direct), but have evolved to exploit female sensory predisposition towards some stimuli. Females of many animals have pre-existing biases towards specific stimuli (such as feature detectors for prey items or food plants) and are attracted to male courtship displays that incorporate or exaggerate such stimuli. For example, in the fiddler crab, *Uca musica*, some males build mud 'hoods' at the entrance to their burrow. Females are attracted to those males whose burrows have hoods because such objects are used by females to hide from bird predators.

There is evidence that all three types of female choice occur and that they are not mutually exclusive but may operate simultaneously. For example, in house finches females that choose males with larger, redder plumage patches obtain direct benefits because these males offer better paternal care for nestlings. Male redness is also heritable, so it is possible that females gain genetic benefits for offspring as well, e.g. higher growth rate.

Finally, it should be noted that females are not the only sex to exercise choice. There are a few species where male investment in a reproductive event exceeds that of females, which results in the sex roles being reversed. When males are a limiting resource for females (e.g. species where males care for the offspring of a single female or where there is a significant cost associated with sperm production), females compete for males and may develop ornaments and courtship displays. Males, on the other hand, are selective about their choice of mate. Complete sex role reversal occurs in several fish species (e.g. seahorses and pipefish), dendrobatid frogs and several bird species (e.g. spotted sandpiper and jacana).

To summarize, the biological function of courtship behaviour is to ensure successful mating occurs between conspecific members of the opposite sex. Within this framework location of potential mates, sexual arousal in partners, synchronization of mating and choice of mating partner are all integral parts of courtship behaviour.

Crepuscular activity

Behaviour that is most common during the periods of dawn and dusk is described as being crepuscular. This is in contrast to **diurnal** (daytime), **nocturnal** (night) and **cathemeral** (at periods during both day and night) periodicities of behaviours. As such the timing of crepuscular behaviours is probably controlled endogenously, but these are linked to exogenous factors such as temperature changes or, most commonly, changing light levels. Additional factors such as risk of predation or foraging efficiency at dawn and dusk may also influence the crepuscularity of behaviours. In the murid rodent *Arvicanthis ansorgei*, its crepuscular behaviour is correlated with distinct peaks of the adrenal **steroid hormone** corticosterone, indicating a hormonal basis for its increased activity at these times of day.

There are several obvious examples of crepuscular activity. The first is the dawn chorus, when usually passerine birds in broad-leafed woodlands at temperate latitudes concentrate most of their singing during dawn and dusk. There are two adaptive reasons for this crepuscular activity. First, the acoustic properties of the air, particularly at dawn, are suitable for the effective transmission of bird songs at the commonest frequencies, because air turbulence is minimized and temperature gradients are ideal. For example, the recorded songs of the white-throated sparrow, *Zonotrichia albicollis*, and the swamp sparrow, *Melospiza georgiana*, were transmitted through open grassland and closed forest. It was found that the signal transmission quality of the songs was more consistent at dawn than at midday. The signal transmission quality is probably essential for the identity function of a bird's song. However, the swamp sparrow's song was more consistent over increasing distances up to 100 m compared with that of the white-throated sparrow. The dawn chorus also appears to have an important territorial function compared with diurnal singing, which aims to attract females (see: **Courtship behaviour**). Temporary removal of rival males surrounding the territory of a male chipping sparrow, *Spizella passerina*, led to a cessation or reduced singing at the dawn chorus, but did not affect diurnal singing. The return of a single rival male led to a resumption of normal singing at dawn.

P.149

Secondly, this is a period of the day when the colour vision of birds is less effective, so they are less able to forage effectively. Insect prey may also be inactive owing to low temperatures and hence would be difficult to locate. However, this may depend on the abundance of food. In experiments with great tits, *Parus major*, it was found that when food was abundant and easy to find, great tits would be less likely to sing or chase away rival birds trespassing on their territories. Therefore, they concentrate their singing at the time of the day when its transmission is most effective and foraging is least efficient.

Mammalian predators such as lions, *Panthera leo*, often hunt crepuscularly. In the Serengeti activity increases dramatically at dusk and is maintained throughout the night, when it declines equally dramatically at dawn. Most of their hunting occurred just after dark, between 19.00 and 20.00 hours and

in the early morning, between 02.00 and 04.00. At dusk mammalian vision is changing over from the daytime, cone-mediated type to the nocturnal, rod-mediated type. Neither is working at its greatest efficiency, so that prey species often have great difficulty in seeing predators. Therefore, hunting efficiency is often greater at dawn and dusk. The behaviour of potential prey animals is similarly influenced by the crepuscular and nocturnal behaviour of predators. For example, African buffalos, *Syncerus caffer*, all stand and become much more vigilant at dusk and can only relax again at dawn.

A less obvious example of crepuscular activity is animals utilizing microorganisms to digest their food. They gain an advantage by extending their feeding activity into the crepuscular period to maintain substrate at consistent levels compared to just diurnal feeding.

Bats emerge from their roosts at around dusk, but their actual time of emergence will depend on their flight ability and feeding ecology. For example, noctules, *Nyctalus noctula*, emerge on average 5 min after dusk, but the long-eared bat, *Plecotus auritus*, only takes flight after almost 1 h (54 min on average). Emergence times are a compromise between emerging early enough to get enough food to survive and emerging too early and being at risk of being preyed upon. Noctules depend on the dusk peak of flies, but are fast and high flying, so that their risk of **predation** is lower than that of slow-flying species such as the long-eared bat, which gleans moths and non-flying prey from tree vegetation. These prey can be found throughout the night, and so the long-eared bat plays it safe and emerges much later to minimize predation.

Nightjars and related birds also hunt at dawn/dusk and through the night. Field studies of the standard-winged nightjar, *Macrodipteryx longipennis*, and long-tailed nightjar, *Caprimulgus climacurus*, in the bush savannah of West Africa have shown that their foraging activity is highly crepuscular; peak foraging occurs at dusk, there is less at dawn and least activity through the night. This pattern of foraging activity correlated with the activity of the nightjars' insect prey. Dusk foraging intensified in periods during the new moon, when lack of moonlight precluded nocturnal foraging.

Swallows, martins and bats often fly over fresh water at dusk in pursuit of insect prey. Many aquatic insects are polarotactic, i.e. they detect aquatic habitats by seeing how they reflect polarized light. At dawn and dusk the sun is low in the sky, and this provides the maximum ability to detect water surfaces polarotactically. However, it is only at sunset that air temperatures are sufficiently high to allow the swarming flights of aquatic insects that attract aerial crepuscular predators.

Visual communication may also be influenced by crepuscular activity. Another nightjar species, the common nighthawk, *Chordeiles minor*, has white patches on its wings, tail and throat, which are important in sexual and agonistic communication. The white patches on the wings and tails of males increase with age, supporting their role, combined with flight displays, in visual communication at low light levels at dusk.

Like humans the great apes are diurnal species, which must limit their nocturnal behaviour, because their eyes are adapted for colour diurnal vision. Because they must maximize their diurnal foraging, an important crepuscular behaviour of chimpanzees, *Pan* spp., and gorillas, *Gorilla* spp., is the construction of nests to rest in during the night. Rather than returning to a particular site, chimps construct their nests close to where they have been feeding. Chimpanzees construct a new nest each night by selecting a stable base in a tree 9-12 m above the ground, then bend in larger branches to which are added smaller branches and leafy vegetation to create a green mattress. This crepuscular behaviour allows chimpanzees' maximum flexibility in their diurnal foraging.

Crib-biting (cribbing)

Crib-biting and wind-sucking are the most common equine oral stereotypies (others include lip-licking, licking the environment and self-biting). The distinction between crib-biting and wind-sucking is often blurred because there are different definitions in several English-speaking countries. For example, in the UK, wind-suckers are distinguished from crib-biters because they do not hold on to fixed objects while engulfing air, whereas in Australia wind-sucking includes grasping and engulfing air. The critical unifying feature of these responses is the characteristic arching of the neck, a posture that allows horses to draw and transiently hold (i.e. engulf) air in the cranial oesophagus. Although horses prefer to grasp wood rather than metal (perhaps because it cushions their teeth), they will crib-bite on metal if no other substrate is available. Often confused with crib-biting by novice observers, wood-chewing is not a stereotypic behaviour since it is not invariant and is seen in free-ranging horses, and so is likely to have a function in digestion or nutrition. That said, it has been suggested that the function of crib-biting may also relate to digestion by generating saliva that may buffer gastric acid accumulation resulting from intermittent feeding of **concentrates**.

The prevalence of wind-sucking/crib-biting in UK Thoroughbred populations has been estimated at 4.2%, and in several countries has been shown to be greater in Thoroughbreds than in other breeds. However, it remains difficult to separate the effects of management and breed because, although they are among the most reactive of breeds, Thoroughbreds are generally raced and therefore managed very intensively.

Like other stereotypic behaviours, crib-biting is not recognized in free-living feral horses but is not purely a product of **domestication**, since it is reported in captive examples of wild equidae such as the onager (*Equus hemionus onager*), mountain zebra (*E. zebra*) and Przewalski horses

P.150

(*E. przewalskii*). Management practices that depart from the trickle feeding typically found in free-ranging equidae, such as feeding discrete concentrated meals that require little mastication, have a greater effect than housing practices on the incidence of crib-biting, but a single causative factor is rarely identified in its aetiology. It is not clear why some horses start crib-biting and others do not, despite being managed identically. If a horse exhibits one oral stereotypic behaviour, it has a greater chance of having a second oral stereotypic behaviour, when compared with normal horses. Some ethologists maintain that, far from being undesirable, horses that go on to perform stereotypic behaviours are simply fortunate since they may have a response, albeit an imperfect one, to the insults of intensive management.

There has been much debate about the function of stereotypic behaviours (Mason, 1991). One influential school of thought argues that they enable animals to cope with stress. For example, transient decreases in heart rates have been demonstrated in association with bouts of crib-biting, and measures to prevent crib-biting are linked to increases in some physiological stress parameters. However, in contrast, it has also been suggested that crib-biters may have higher basal sympathetic activity because they have a higher overall mean heart rate (Minero *et al.*, 1999). Experimental studies to assess the validity of the stress-coping hypothesis in several species have produced equivocal results.

Stereotypic behaviours may help horses cope with suboptimal environments or provide direct and immediate rewards that bring their own intrinsic gratification, possibly through **endorphin** release, which has been implicated as a possible source of reinforcement for crib-biting. **Opioid** antagonists can reduce crib-biting significantly, which suggests that at least one of the perceived benefits of crib-biting (from the horse's perspective) is mediated by opioids. However, resting behaviour in crib-biters also significantly changes with opioid antagonists, so the reduction in crib-biting may occur because of generalized sedation. Furthermore, there is recent evidence that stereotypic horses persist in non-rewarding activities longer than control horses (Hausberger *et al.*, 2007; Hemmings *et al.*, 2007), possibly reflecting alteration of basal ganglionic activity (Hemmings *et al.*, 2007).

It is also possible that a given stereotypic behaviour may retain a function within the motivational system from which it is derived. So, crib-biting may provide a route to normal feeding and digestive activity within environments that limit normal forage intake (e.g. an intensive training programme characterized by the provision of diets with a high concentrate:roughage ratio). Support for this possibility has come from a prospective study of a population of foals, which showed a peak in the emergence of crib-biting at 20 weeks of age (Waters *et al.*, 2002). This coincided with a significant increase in the feeding of concentrates. Foals and adults have been shown to crib-bite less when fed antacid supplements.

Horse lore emphasizes the importance of mimicry rather than environmental deficits, believing that exposure to a stereotypic neighbour may increase the likelihood of the behaviour's development or performance. Such social influences, known in bank voles, may also affect stereotypic behaviour levels in horses, despite there being no current indication that horses can learn by observation. Even if **observational learning** is not involved, the possibility that having a stereotypic neighbour may arouse observing horses and so predispose them to developing stereotypic behaviour cannot be ruled out. Since crib-biting is popularly regarded as being transmissible by mimicry and is associated with health problems, horses exhibiting it are often isolated. Wind-sucking (but not crib-biting, due to its possible confusion with wood-chewing) must be declared at some auctions in the UK and tends to lower the value of affected animals.

The deleterious effects of crib-biting vary, with some owners reporting no ill effects while others regard diminished performance, digestive disorders, incisor erosion and failure to thrive as important sequelae. Some veterinarians maintain that crib-biting leads to chronic colic, flatulent colic and a distended abdomen. This is supported by epidemiological evidence that epiploic entrapment is associated with a history of cribbing/wind-sucking (Archer *et al.*, 2004). However, the extent to which these signs can be linked directly to aerophagia has been challenged by radiographic studies indicating that negligible gas is ingested during crib-biting (McGreevy *et al.*, 1995). It is possible that crib-biters have concurrent gastrointestinal disturbances that cause these signs.

The need to prevent stereotypies for aesthetic and occasional health reasons has prompted searches for permanent cures (see: Collar). Physical or surgical approaches that are commonly attempted to prevent crib-biting vary considerably in success. Surgery is falling from favour as the causes of oral stereotypic behaviours - and especially the role of gastric acidity in its ontogeny - are becoming recognized, but a humane remedy that is effective for every crib-biter remains elusive. It seems that the continual reinforcement of stereotypic behaviours contributes to their resistance to therapy. Data demonstrating increasing prevalence with age suggest crib-biting can become emancipated from its initiating causes. So, while stereotypies may arise in response to adverse management, they may persist in more enriched environments. That said, it is better to implement environmental **enrichment** programmes prophylactically rather than therapeutically. Notwithstanding their effects in maintaining normal behaviour in youngstock, they are also likely to increase learning ability while, at the same time, promoting musculoskeletal health.

Critical period

In general, a critical period is a limited time in which an event can occur that will result in a lasting change. From an animal behaviour point of view it refers to the early stages of an animal's life in which the animal is particularly sensitive to certain types of experience or stimuli. Exposure to the correct stimuli during these early life stages will result in appropriate, species-typical behavioural changes; while animals that were not exposed to the stimuli or were exposed to inappropriate stimuli during the critical periods may not perform certain behaviour patterns or may display them inappropriately later in life. There are criteria that must be met for an early stage of development to be called a critical period: (i) they must have set beginning and end points; (ii) there must be an intrinsic effect - something in the animal must change so that experience that formerly had an impact on behaviour can no longer affect the behaviour; and (iii) the extrinsic stimuli or experiences must be identifiable.

Critical periods are especially important during **imprinting**. One of the best-known examples comes from **Konrad Lorenz**, who demonstrated that greylag geese would imprint on the first suitable moving stimulus they saw between 13 and 16 h after hatching. Lorenz was able to imprint the geese on himself and is often pictured with a line of goslings following him. The term critical period is now generally replaced by **sensitive phase**. Critical periods are characterized by abrupt beginnings and ends and, if the appropriate experience is not achieved during this time period, the animal will not be able to learn the correct behaviour; in contrast, sensitive phases have gradual beginnings and ends and, while they are the period of maximum sensitivity in which the appropriate experience may occur, the correct behaviour may still be potentially learned at a later stage.

Ensuring an animal receives the appropriate early experiences is important for the development of later behaviour patterns. However, with the **intensification of animal production**, many animals are not kept in natural surroundings and do not experience the correct stimuli during these critical periods. As a result, their behaviour may also be altered and different from their wild or less intensively raised counterparts. In some cases this can result in suboptimal behaviour, but the differences are not necessarily of welfare significance. However, from a conservation perspective the failure of filial and sexual imprinting during critical periods can have catastrophic effects on attempts at successful and sustainable **reintroduction**.

Critical temperature

Animals perceive thermal information in the form of extreme ambient temperatures, relative humidity or wind speed (or a combination of these), which are detected by thermoreceptors, skin dryness (particularly in the throat and nasal passages) and mechanoreceptors, respectively. The optimum temperature is usually referred to as the comfort or thermoneutral zone, above and below which (the critical temperatures) animals have to work physiologically to sustain their core body temperature, through increasing either heat loss or production. They learn the importance of being in an optimum temperature, and young animals are more likely than older animals to use areas where the ambient temperature is below the comfort zone; older animals learn to use favourable microclimates and exploit exposed areas at times when ambient temperatures are increased.

Cold temperatures are generally less of a problem than excessively hot ones. For example, the lower critical temperature of adult cows is -23°C and, at sub-zero temperatures, the availability of fodder is more of a problem than the temperature. However, they are prone to heat stress, especially if they have a high metabolic rate because of high productivity and/or consume a high-fibre diet that produces considerable heat. Initial responses to high temperatures include increased respiration rate, which occurs as low as 21°C, but further increases in temperature (above 25°C) reduce food intake and hence the heat of digestion.

Perception of temperature, as with most other stimuli, is relative rather than absolute. Response to localized thermal loading to one part of the body is reduced if the ambient temperature is low. There are genetic differences in the susceptibility of animals to thermal load, which may derive from differences in perception, but are more likely to derive from differences in endogenous heat production and heat dissipation. For example, Holstein-Friesian cattle are particularly prone to heat stress, compared with *Bos indicus* cattle, but mixed groups may follow the less resistant cattle in reducing grazing time. Pigs and poultry have less endogenous heat production than ruminant animals and are therefore more susceptible to cold temperatures.

Critically endangered

A species of animal or plant is considered critically endangered when, generally speaking, its prospects for survival in the wild are so poor that special measures must be taken to prevent its **extinction**. A more formal definition is provided by the International Union for the Conservation of Nature (IUCN). There are several criteria and sub-criteria, but these include a reduction of the population by more than 90% in the

P.152

preceding 10 years, a geographic range of less than 100 km² and a population of fewer than 250 mature individuals.

(RS)

IUCN Redlist. Available at: <http://www.iucnredlist.org>

Cropping of ears

Cropping of ears involves the surgical removal of a distal portion of both of the ears of a dog, usually specific breeds such as boxers, Great Danes, Dobermann pinschers and schnauzers. The historical reasons for ear cropping are similar to those for tail **docking**. The aim was to reduce injury to the ears and to make it harder for such dogs to be caught by the ears. The practice was common in dogs bred for guarding, fighting and **hunting** of small animals. Although few dogs are used for certain of these purposes now, some breed fanciers argue that cropped ears are an inherent part of the historical breed standard. However, others regard the practice of ear cropping as an unnecessary and painful **mutilation**. In many countries, including Australia, Belgium, Denmark, Finland, Germany, the Netherlands, Norway, Sweden and the UK, the practice is banned under prevention of cruelty to animals' legislation.

(BJ)

Cross-suckling

In 'nature', unweaned animals obtain their milk by suckling from their mothers. Occasionally, however, animals may suckle from animals other than their mother. For example in cattle, this can involve an unweaned calf suckling from a lactating cow other than its biological mother, a calf sucking on another calf or weaned calves and even adult cattle suckling another lactating cow (also called 'milk stealing' or 'inter-suckling'). However, the cases that have received most attention from researchers involve unweaned calves suckling at other calves (see Fig. C.16).

Unfortunately, there is inconsistent use of the terms 'cross-sucking', 'cross-suckling' and 'inter-sucking', which are often used interchangeably. Terminologically, 'suckling' is usually used to describe the suite of behaviours that the neonate performs during **nursing**, and tends to imply milk transfer. Although actual sucking is the most obvious of these behaviours, and is the consummatory behaviour that is the most essential to ensure milk transfer from the mother to the young, other appetitive behaviours besides sucking (such as butting the udder, switching teats, stripping teats, etc.) do occur. Most often, the sucking between unweaned animals, where no milk can be transferred, is referred to as cross-sucking, a usage that we follow here. Inter-sucking tends to be used to describe sucking involving older including adult animals.

Fig. C.16. An example of cross-sucking between two unweaned dairy calves.

When kept with their mothers, the young of many species almost exclusively suckle from them. However, when the mother is absent (e.g. as a result of **death** or removal), they may attempt to suckle from other lactating animals. In cattle, usually, these attempts are unsuccessful, since cows are capable of recognizing their own offspring and reject suckling attempts by other calves. Occasionally, such attempts are successful, particularly if the calf attempts to suckle from behind rather than from the side, which is the more normal position. An approach from the rear may make it more difficult for the mother to detect by smell that the calf is not her own. In some cases, however, cows will adopt another calf and allow it to suckle freely in the normal position. Use of such 'nurse cows' is a common feature of some types of cattle rearing (e.g. dualpurpose cattle rearing in many tropical countries). Interestingly, such cases of suckling do not have the same physiological effects on the cow (e.g. those resulting in prolonged lactation or anoestrus) as when the cow is suckled by its own calf. This suggests that it is the psychological component

of the mother-offspring bond which is important for these physiological effects rather than the suckling and milk transfer itself.

Although beef cattle usually suckle from their mother, most dairy and veal calves (at least in most industrialized countries) are separated from their mothers soon after birth and are fed

P.153

milk either from a teat feeder or from a bucket. In the case of bucket feeding, they have little opportunity to actually suck in order to obtain their milk. How much of a threat to their **welfare** does this constitute? Calves that are housed individually and fed milk from a bucket suck avidly at the bucket, bars of the pen, chains, bits of rubber, ears and mouths of other calves - or indeed almost anything that they can get into their mouths. When milk-fed calves are housed in groups, calves will often suck at the belly, inguinal area or the mouth and ears of another calf (**see: Vacuum behaviour**). Similar sucking behaviours have also been documented in other species when they are early weaned and/or hand reared, e.g. cats and horses, but it is in cattle that most research into this problem has been conducted.

The occurrence of such behaviour may have implications for the welfare of animals in a number of ways. First, many researchers have suggested that young 'need' to suck and that providing milk from a bucket or other source is not sufficient to ensure good welfare, even if the animals' nutritional needs are met. Cross-sucking therefore may be a sign of behavioural deprivation (**see: Behavioural need**). Secondly, cross-sucking may lead to injuries (including teat damage, when the behaviour is directed at other animals) and drinking urine directly from another calf, in the case of cattle. Finally, some of the ways in which this behaviour is controlled may themselves have detrimental effects on animal welfare. For example, many dairy farmers believe that cross-sucking by milk-fed calves will lead to 'milk stealing' from lactating cows when these calves grow up.

For these reasons, the occurrence of cross-sucking discourages dairy producers from keeping milk-fed calves in groups, despite the animal welfare (and labour) advantages of this form of rearing. A number of physical devices have been developed and used to prevent cross-suckling by older animals, especially to prevent milk stealing in cattle. These are generally attached to the muzzle of the initiator or (less commonly) to the udders of the recipients of the behaviours, and are designed to physically prevent the animal sucking. In some cases surgical intervention has been used, e.g. slicing the tongue of the animals. There have been few systematic studies of the effectiveness of such techniques, which in all cases require some labour and expense, and will cause distress to the animals. Surgical interventions, in particular, are ethically questionable and are illegal in a number of countries (**see: Mutilation**). It would be far better to be able to limit the incidence of cross-suckling through understanding the causes of the behaviours and developing feeding and housing systems that prevent it occurring.

Considerable research has now been carried out to try to understand the causes of cross-sucking between unweaned calves in particular, and to find means of preventing it. To be able fully to control cross-sucking (and to decide on the importance of sucking deprivation for animal welfare), we need to understand better the causes and consequences of sucking behaviour (**see: Motivation**). Why do calves suck and what satisfies their sucking motivation? At a simple level, the motivation to suck would seem to result from the calves' hunger and, under normal circumstances, the performance of sucking, leading to the ingestion of milk, would reduce this hunger.

However, research results have recently demonstrated that this model is over-simplistic, or at least does not apply to cross-sucking. For example, most cross-sucking in group-housed, milk-fed calves occurs around the time that the animals drink milk. Nevertheless, in contrast to what might be expected, the occurrence of cross-sucking is highest immediately after the meal rather than before the meal. This is the opposite of what we would expect if hunger was the main motivation. Furthermore, cross-sucking is reduced when the calves can suck a dry teat after the meal, even if this does not alter the amount of milk drunk by the calf. Finally, cross-sucking can be greatly reduced (and will almost disappear) when the

calves are weaned off milk. Clearly, young calves do not suck simply because they are hungry, and drinking milk is not the only factor that reduces their sucking motivation.

If it is not hunger, what is it that motivates calves to suck and what can be used to reduce this motivation? When milk-fed calves are given milk to drink, they will often suck a dry teat once they have finished drinking. This non-nutritive sucking is thought to be similar to cross-sucking (except that it is directed to a dry teat rather than to another calf).

Research using this behaviour has allowed us to answer some of the questions about sucking motivation. First, sucking motivation seems to be stimulated (rather than reduced) by the ingestion of milk, at least in the short term. When calves drink milk from a bucket they are then highly motivated to suck on something. Experiments that have varied the concentration of the components of milk show that it is primarily the taste of lactose (or sugars) that stimulates sucking in this way. The quantity of milk drunk does not seem to be very important. This sucking motivation is reduced if the calf can suck at something, even if no milk is ingested. Thus, it is the performance of the sucking behaviour itself, rather than the ingestion of milk, which reduces sucking motivation. If the calf cannot suck at anything, the sucking motivation gradually declines over the following 10 min. Together, these facts explain why cross-sucking occurs most often soon after the milk meals, why it is high if calves drink their milk without being able to suck and why allowing the calves to suck a dry rubber teat can reduce cross-sucking.

Using this information, we can develop feeding management systems for calves that allow us to control and limit the amount of cross-sucking. The most important aspect is to allow the calves sufficient opportunity to suck for long enough to satisfy their sucking motivation, either during or after the ingestion of milk. For example, use of automated milk feeders or other teat-feeding systems (such as a bucket fitted with a teat) that allow the calves to suck their milk reduces the incidence of cross-sucking. Even providing a dry teat after the meal can substantially reduce cross-sucking. However, the use of teat-feeding systems is not invariably associated with reduced cross-sucking, suggesting that the details of feeding management are important.

Automated milk feeding systems can be designed to allow the calves to suck the teat for a sufficient time after the meal to satisfy their sucking motivation. For example, cross-sucking is increased if teat-fed calves are not able to continue to suck the teat after milk ingestion, but a swing door can prevent calves from being displaced from the teat by other calves, which allows them to perform longer bouts of non-nutritive sucking

P.154

on the teat and results in a lower incidence of cross-sucking. Displacements of calves from the teat feeder can also be reduced by feeding the calves a larger quantity of milk. Slower rates of milk delivery can reduce the incidence of cross-sucking. Simply restraining calves so that they cannot suck at other calves for 15 min or so after a milk meal can help reduce the incidence of the behaviour. However, this leads to calves remaining highly motivated, but unable to suck, which is not ideal for their welfare (**see: Frustration**). In any case, techniques to prevent cross-sucking are most effective the earlier they are implemented: once calves have learned to suck at other calves, the habit is much harder to break.

It is important to remember that sucking is a vital behaviour for the survival of young mammals, so it is not surprising to find that they are highly motivated to suck. Simply providing an adequate quantity of milk, but without letting the animals actually suck at something, is not sufficient. Research has shown that calves that can suck to obtain their milk lie down sooner in more relaxed positions than calves that drink their milk from a bucket. Furthermore, the secretion of hormones associated with digestion and metabolism, such as **insulin** and **cholecystokinin**, has also shown to be increased when calves can suck a teat.

Milk stealing is most often a problem when weaned animals, including adult cows, suckle from lactating cows that are kept for milking. In such cases, the animals have been reported to drink many litres of milk

per day, making this a problem with considerable economic potential. Milk stealing has been reported to be associated with more frequent teat injuries and may increase the chance of **mastitis** from certain bacteria (e.g. *Corynebacterium pyogenes*). The incidence of this behaviour within herds of lactating animals varies greatly. Surveys in Sweden and Switzerland reported that the majority of farms had some problems with milk stealing, but often only a few cows were involved. The incidence is most often reported to involve somewhere between 0 and 10% of the animals, although on some farms over 50% may be involved. The few reports on this behaviour that are available suggest that certain animals are far more often involved (both as recipient and initiator) than others, and that certain pairs of animals appear to be involved more often than others. There has been little systematic research done on this behaviour, perhaps because the relatively low rate of occurrence makes it difficult to study. Epidemiological surveys have so far produced no consistent findings as to the effect of housing or feeding management on the occurrence of the behaviour. Surveys have reported that milk stealing by cows tends to be more common on farms that have a higher incidence of cross-sucking between calves and between older heifers, but the causal link between these behaviours is unclear. A low feed allowance at weaning appears to be implicated. Apart from the suggested link to teat injuries and mastitis, we have little information as to whether milk stealing is important for animal welfare, despite its obvious economic importance.

Crypsis

All traits that reduce an animal's risk of becoming detected when it is perceivable to an observer represent crypsis. This definition distinguishes crypsis from hiding and masquerade (mimicry), the primary function of which is to prevent recognition. Visual crypsis can encompass background matching, whereby an animal matches the colour, contrast and texture of the background, self-shadow concealment (countershading) and disruptive coloration, in which markings create false edges that hinder detection of the true outline of the animal.

In order to match the background some animals attach substrate to their bodies (for example, caddisfly larvae) or even other animals and plants (for example, decorator crabs attach anemones, coral polyps and seaweeds to their exoskeletons). Some animals are able to change colour and texture incredibly quickly.

Cuttlefish have groups of coloured chromatophores (cells containing pigment granules enclosed within an elastic sac) that can change in size via muscular contractions, enabling the animal to change colour very rapidly. Crypsis may also be non-visual. Many animals (especially insects) use a chemical disguise to prevent detection. For example, the caterpillar of the moth *Biston robostum* avoids predation by ants by having a cuticular chemical signature that resembles the host plant upon which it feeds. However, the fact that the chemical signature resembles the host plant makes it difficult to distinguish between crypsis and mimicry.

Culling

Culling is the selective **slaughter** of a number of animals. This has been a traditional practice in the human relationship with animals throughout history. The deliberate removal of unwanted stock has led to the development of the breeds of domesticated animals that exist today, through the culling of undesirable animals and their removal from the gene pool. Current practical **breeding** programmes for desired traits, involving minimization of phenotypic standard deviation (through the use of best linear unbiased prediction (BLUP)), necessarily involve a large proportion of each generation being discarded, and often culled.

Culling is a normal husbandry practice to remove from herds or flocks animals that are no longer productive, or to remove undesirable animals from the breeding stock. Commonly, 20-25% of stock are culled from groups of animals annually. Poor fertility is the most common cause for culling in dairy herds in the UK (Esslemont and Kossaibati,

P.155

1997), sheep (although **mastitis** is also a significant cause) and sows. Other reasons for culling livestock include: (i) poor levels of production (growth, egg laying, litter numbers, milk yield); (ii) poor mothering ability; (iii) difficulties during **parturition**; (iv) poor performance of offspring; (v) **disease** (acquired and inherited); (vi) **lameness**; (vii) other physical abnormalities; (viii) poor sight; (ix) weakness; (x) poor condition; (xi) old age (including reducing generation length to maximize genetic gain); and (xii) being the wrong sex. In sheep, additional reasons include undesirable characteristics of the fleece and 'broken mouth' (inability to graze efficiently). Culling on a large scale is an epidemiological defence against disease threatening livestock (examples include Newcastle disease and avian flu in poultry, swine fever in pigs, foot and mouth in cattle and sheep and infectious pancreatic necrosis in salmon). In addition, culling provides protection against diseases threatening other animals, including humans (for example, the culling of dogs and wild canids during outbreaks of rabies).

Welfare concerns may also lead to culling of stock. Disease, parasitism and inherited or acquired bone or muscular deformities may cause a permanent state of **suffering** in an animal. Examples might include bone deformities, joint fracture or trauma causing pain in broiler chickens, scrapie and **footrot** in sheep and mastitis and lameness in dairy cattle. Indeed, in this regard a high rate of culling may reflect good welfare management - demonstrating a keen awareness by the **stockperson** of the suffering of their stock and efforts to eliminate, or at least not prolong, that suffering. Culling animals that are genetically predisposed to excitability or nervousness during **transport** and handling can reduce the **stress** experienced by future generations of animals during these procedures. Therefore culling per se is not

necessarily an indicator of poor welfare, especially considering that a dead animal is not a suffering animal. However, culling diseased animals is a costly and unnecessary exercise if the animal is otherwise productive and the problem is treatable. Replacement animals will need to be paid for and these come with no disease-free guarantee. The culling of animals simply because they have an infection should be carefully considered and the specific agent identified; for example, mastitis infection by *Streptococcus agalacticae* is relatively treatable compared with *Staphylococcus aureus*. Animals may be also culled for demonstrating undesirable behaviours, such as inter- or intraspecies **aggression**.

Culling is also used as a tool in the management and **conservation** of populations of animals in the wild or in animal collections. Animals are removed from captive populations by culling when they are surplus to the holding capacity of a **zoo** or animal park. It is a measure used to ensure balanced social dynamics in respect of age and sex, to prevent the spread of disease - including the spread to domesticated animals; for example, the culling of badgers (*Meles meles*) in the UK is a perceived attempt to reduce the risk of bovine tuberculosis to domestic cattle. Wild animals may also be culled to reduce the risk of genetic contamination, the inadvertent mating of domestic animals by the wild type (such as wild boar with domesticated pig breeds).

Culling is also used to reduce the environmental pressures concomitant with overpopulation of groups of animals in the wild. Indeed, the practice of culling animals in the wild is further defended as a means of supporting the stronger members of a group by removing the weaker. Non-native species may be culled to reduce environmental pressures on preferred native species, examples being the red (*Sciurus vulgaris*) and grey (*S. carolinensis*) squirrels in the UK; or to prevent hybridization of pure native species with non-native species (the ruddy duck, *Oxyura jamaicensis*, and the white-headed duck, *O. leucocephala*, in Europe).

Animals are also culled to protect plants of particular value - either cultivated crops, grassland (in particular rabbits, *Oryctolagus cuniculus*) or botanical specimens of special interest (which includes the culling of various species of deer in Europe and the flying fox, *Pteropus poliocephalus*, in Australia). Wild animals are also culled to prevent damage to fencing designed to keep out/in predators/livestock (elephants in African reserves and camels damaging Australian dog fencing). Culling of wild animals can also provide a source of income for local human populations, through the attraction of shooting or safaris for tourists, or the value of the carcasses, including the harvesting of ivory from elephants.

Culling of wild carnivores is also practised throughout the world to prevent predation of livestock (including the culling of seals to protect wild fish stocks) and the dangers some animals pose to humans. Stray animals, particularly dogs, are culled, as are verminous animals, a group that can include rats, mice, moles, rabbits, stoats, mink, pigeons and innumerable invertebrate species, depending on an individual's definition as much as national legislation. For example, vermin are not defined in UK law.

Unwanted **draught animals**, racing dogs, other working animals and **pets** are routinely culled, including those that have outgrown their usefulness and those deemed not to have 'made the grade' at an early age. **Laboratory animals** are commonly culled following completion of scientific procedures.

Culture

Culture is broadly defined as behavioural traits, shared by a population or subpopulation, that are acquired through **social learning** (i.e. learned from others through observation or interaction) and transmitted within or between generations (i.e. horizontal versus vertical transmission). Several reports have been made of cultural behaviours among various animals such as primates, cetaceans, birds or fish (e.g. tool use, foraging behaviour, vocal dialects). One of the best-known examples is probably the sweet potato washing first observed 50 years ago in the Japanese **macaque** population of Koshima, that has not been seen in other populations of macaques.

However, the question of animal cultures is still the subject of debate mainly based on the definition of the term 'culture'. Although the broad definition above has been adopted by many researchers working with non-humans, some psychologists restrict it to transmission only through **imitation** and teaching, and thus name it 'tradition' in animals rather than 'culture', while others prefer to use the term 'proculture'.

According to the definition of psychologists, in order to speak of culture in animals, one should demonstrate that the

P.156

transmitted behaviour is not a result of any social learning process such as **local enhancement**, for instance, but stems only from an imitation process. If there is increasing experimental evidence that some animals have good imitation skills, no conclusive proof of such social learning could be drawn from observations in the wild populations demonstrating so-called cultural behaviours.

Ethnographic methods are an alternative approach that, in this case, tries to demonstrate that a behaviour is cultural by excluding all alternative explanations such as individual rather than social learning, ecology or genetics. This approach favours a categorical perspective, whereas behavioural variations can probably result from a combination of several factors. Alternatively, **translocation** of individuals between populations or of populations of animals between sites has been carried out successfully in fish to demonstrate culture.

Cynomolgus monkey

Macaca fascicularis (also known as long-tailed macaque, crab-eating macaque, Java monkey) is a diurnal, arboreal macaque, native to forest areas of South-east Asia and introduced into Mauritius over 300 years ago. It is primarily used in drug development and testing in the USA, Western Europe and Japan. *M. fascicularis* is now almost as widely used as the rhesus macaque, *M. mulatta*, in some areas of academic research, e.g. neuroscience. *M. cynomolgus*, *M. irus* and *M. philippensis* are names that were formerly used for this species.

Cytokines

Cells of the immune system communicate with each other, and with other organs and tissues, using cell signal proteins termed cytokines. Cytokines induce and orchestrate the specific response necessary to combat the threat (be it a pathogen or stressor) at hand. Cytokines are predominantly produced by immune cells such as macrophages, dendritic cells and T-cells of the lymphocyte population. Cells of the immune system and other tissues contain receptors for these cytokines that lead to further cell signals and cellular activation. These receptors may be on the cell surface of the recipient cell or the receptors may be soluble. Some receptors are functional and activate the recipient cell, while others are decoys and play an important role in regulation of the immune response. Cytokines can be grouped by function, including acute phase cytokines, immune response cytokines and haematopoietic growth factors. Another very important group of cell signals are the chemokines, with the primary functions of cell recruitment and trafficking.

Acute phase cytokines are produced when a pathogen or injury is detected. The first group are inflammatory mediators and include **interleukins** (IL)-1 α and -1 β , IL-6 and IL-8; tumour necrosis factors (TNF)- α and - β ; and macrophage chemotactic proteins (MCP)-I and -II. IL-1 has receptors on many tissues, including the **brain** and liver. Between IL-1 and TNF- α , sickness behaviours such as anorexia, fever and somnolence are induced. Interestingly, IL-1 production in response to stressors is species- and stressor-specific (restraint stress and isolation stress induce IL-1 differently). IL-6 and IL-1 stimulate production of acute phase proteins by the liver, which act to bring the animal back to **homeostasis**. Acute phase cytokines are enhanced with some stressors such as **transport**, **weaning** and food deprivation (**see: Feed restriction**).

The second group contains immune response cytokines. Cytokines involved in activation of Type I or Type II immune responses include IL-2, IL-4, IL-10 (which acts as a suppressor), IL-12 and IL-15. Supporting the production of immunoglobulins are interleukins 2, 4 and 8 by promotion of differentiation of lymphocytes and proliferation, both of which are necessary for a polyclonal antibody response. IL-2, which is produced by T-cells, is also important for B-cell maturation, supporting adaptive immune responses.

Many of the inflammatory cytokines can be destructive if not controlled rapidly. Therefore, several cytokines have a suppressive effect; among them are IL-10, which is instrumental in down-regulating macrophages, and IL-1 receptor antagonist (IL-1RA), which, along with decoy receptors, keeps the IL-1 response from running rampant. Macrophage inhibitory factor, produced by T-cells and pituitary cells, inhibits macrophage migration, stimulates macrophage activation and induces steroid resistance, thereby allowing for lymphocyte differentiation and proliferation and antibody production.

Haematopoietic growth factors constitute another group of cytokines responsible for growth and differentiation of cells. IL-6 is a member of this group, as are IL-11, granulocyte colony-stimulating factor (G-CSF), granulocyte macrophage colony-stimulating factor (GM-CSF), IL-3 and stem cell factor. These cytokines play various roles in maturation and differentiation of immune cells from the bone marrow and in the blood.

Interferons are a group of cytokines with anti-viral properties - IFN- α , IFN- β , IFN- γ and one immune interferon (IFN- γ). Interferons can arrest viral production and even remove them from the infected cells without killing the infected cell. Their role is unique and has proved crucial in therapeutic control of viral diseases in many species.

An additional group of proteins, termed chemokines, is responsible for recruitment of cells to sites of infection or inflammation. Some chemokines recruit and stimulate maturation of dendritic cells (a phagocyte responsible for initiating adaptive immunity). This is a critical process, since Langerhans and

dendritic cells are an entirely different phenotype before their recruitment to immune tissues and maturation. Immature dendritic cells can phagocytize foreign particles, but are not major cytokine producers. After stimulation with chemokines, they lose their ability to phagocytize particles, but become extraordinary antigen presentation cells, stimulating the T-cells with cytokines during presentation, thus engaging the adaptive immune response.

An elaborate control system exists for many of these cytokines. Left unchecked, they would destroy healthy tissues

P.157

and deplete the animal of available metabolic resources. Some receptors are produced in a soluble form to provide additional control, particularly of inflammatory cytokines such as IL-1 and TNF- α . For instance, IL-1 has redundant control. Besides having soluble receptors and an antagonist, a dummy receptor is produced with responses similar to IL-1RA.

Epithelial cells, fat cells, hepatocytes, fibroblasts, osteoblasts, chondrocytes and bone marrow cells are some of the non-immune cells that produce cytokines. Generally, they do not produce cytokines in great abundance - unlike the immune cells - but help to control the immune activity in the microenvironment. For instance, the lungs constitutively express higher IL-1RA than IL-1. Lung tissue is very fragile, so induction of cells is not beneficial under healthy conditions. The hypothalamus has receptors for IL-1 and TNF, but also expresses IL-1 and IL-1RA when necessary. Many immune cells contain receptors for cortisol. Cortisol at low concentrations can stimulate some immune functions, but at high concentrations (acute or chronic) it can be suppressive, resulting in increased susceptibility of the animal to disease. This has been demonstrated by reduced cytokine production under these circumstances.

In summary, cytokines are produced to communicate between immune cells and tissues and with non-immune tissues to elicit an immune response appropriate to the challenge. An intricate maze of controls and counter-controls is in place to drive the animal back to homeostasis. These mechanisms are intertwined with neurophysiological systems, metabolic processes and with the HPA axis (**hypothalamic-pituitary-adrenal axis**) through cytokine communication. Cytokines and chemokines continue to be discovered, so the complexity of the immune communication network is still not fully known.

Dark cutting

Dark cutting is a meat quality defect caused by a lack of the normal acidification of meat during *rigor* development post-slaughter. Between **slaughter** and chilling of the carcass, glycogenolysis occurs in the muscle tissue, which converts glycogen, the muscle energy store, to lactic acid, thus decreasing the pH of the meat. Dark cutting is related to low muscle glycogen at the time of slaughter, which can be indicative of animals having experienced stress during the period prior to slaughter.

Darwin, Charles Robert (1809-1882)

The Society for the Prevention of Cruelty to Animals was founded in London when Charles Darwin was 15 years old. Darwin was actively involved in alleviating pain and suffering among animals, which grew out of his conviction of an evolutionary continuity in emotional states between animals and people. In his autobiography, Darwin reflected on the problems of **vivisection**:

I have all my life been a strong advocate for humanity to animals ... [but] ... know that physiology cannot possibly progress except by means of experiments on live animals [which have been anesthetized, when possible] ... it is justifiable for real investigations on physiology; but not for mere damnable and detestable curiosity.

Charles Darwin was born on 12 February 1809 near the town of Shrewsbury, England. His father, Dr Robert Darwin, was a physician, while his mother, Susannah Wedgwood, was a daughter of the founder of the famous pottery firm. As a young boy, he thrived on wandering in the country, collecting insects and plants, and one of his strongest passions was for birds. He would take notes on their activities, as well as shoot them, which was a common scientific practice at the time. In fact, Darwin was quite a marksman when it came to shooting birds, a hobby that served him well while on the voyage of the HMS *Beagle*.

Darwin's initial career trajectory took him to Edinburgh, Scotland to study medicine, but after a couple of years he changed his mind. He moved to Cambridge, England to study for the clergy but, again, decided against that career. With the support of his uncle, he dropped out of school and became a crew member of the HMS *Beagle*. This vessel sailed from England on 27 December 1831 and re-docked on 2 October 1836. Upon return from his 5-year adventure, Darwin married his cousin, Emma Wedgwood, and settled in London.

While living in London, Darwin took regular trips to the Zoological Gardens, where he made copious notes about animals and quizzed the keepers about their knowledge of animals. One of his main interests at the time was trying to evaluate the **cognition** abilities of apes in an effort to gain insights into the origins of the mental powers of people. An orang-utan named 'Jenny' had arrived at the Zoological Gardens in 1837,

and she became a subject of his work. Darwin recorded her responses to music, mirrors and different food items. But Darwin was not comfortable living in the city, so in 1842 he moved with his family to the countryside in Kent, about 22 km south-east of London. Their residence was called Down House, and he remained there until his death on 19 April 1882.

Charles Darwin's primary contribution to biology was not in inventing the idea of evolution, but in providing a mechanism to account for the diversity of life on Earth, which he called 'natural selection'. His logical arguments were based upon three premises. First, variation within a species is a fundamental aspect of biology. Such reasoning ran contrary to religious fundamentalists, who considered variation as deviations from an ideal model organism. Secondly, differences among individuals in trait expression can be inherited. Although the mechanism of inheritance was not discovered until about 100 years after Darwin's proposal, the transmission of traits from generation to generation was a requirement of natural selection. Thirdly, individuals differ in their reproductive output, either by producing more offspring than others (differential fertility) or by dying sooner than others (differential mortality). The latter concept formed the basis of the idea that 'nature red in tooth and claw' drove evolution.

In essence, Darwin's idea was that changes over time were an outcome of the inheritance of traits that differed across individuals and resulted from differential reproduction. He was so convinced that his model was correct that he proposed a testable hypothesis that, if true, would completely destroy his idea: 'If it could be proved that *any part* of the structure of *any one species* had been formed for the *exclusive good of another species*, it would *annihilate my theory*, for such could not have been produced through natural selection [*italics added*]'.

While best known for proposing a mechanism of biological change over time, Darwin was a voracious reader, prolific writer and incessant correspondent whose insights into natural history resonate today in terms of applied animal behaviour and welfare. One of his early perceptions concerned reproductive processes in captivity. He noted that: '[m]any facts clearly show how eminently susceptible the reproductive system is to very slight changes in the surrounding conditions. Nothing is more easy than to tame an animal, and few things more difficult than to get it to breed freely under confinement, even when the male and female unite.' He puzzled over why 'weak and sickly' animals could breed in the wild, while 'long-lived

P.160

and healthy' animals had problems in captivity. His astute observations remain an enigma today: what is the mechanism whereby reproductive success is hindered in captivity among apparently well-fed and healthy animals?

Darwin's concepts about evolutionary processes enabled him to provide a possible reason why animals in captivity might have reproductive failures. He wrote: 'It is by no means rare to find certain males and females which will not breed together, though both are known to be perfectly fertile with other males and females ... the cause lies in an innate sexual incompatibility of the pair'. Mate choice was a pillar of sexual selection that could have profound implications, not only for variation in reproductive output among wild animals but for reproductive success in captive animals.

In the absence of a clear understanding of genetics, Darwin nevertheless thought that inheritance of traits and genetic relatedness influenced reproduction. One topic he addressed still haunts zoological institutions, i.e. kinship and mating success. He concluded that:

A cross between individuals of the same species, which differ to a certain extent, gives vigour and fertility to the offspring; and that close interbreeding continued during several generations between the nearest relations, if these be kept under the same conditions of life, almost always leads to decreased size, weakness, or sterility. Devising optimal breeding programmes for captive animals that

incorporates genetic information, as well as an understanding of partner compatibility and social adeptness, remains a challenge.

Perhaps Darwin's major foray into setting the framework for animal welfare issues was his perspective on animal emotions. For example, he wrote: 'Animals which live in society often call to each other when separated, and evidently feel much joy at meeting', later commenting that 'Young chimpanzees make a kind of barking noise, when pleased by the return of any one to whom they are attached'. About a century after he wrote these words, field studies of the natural behaviour of wild chimpanzees revealed that reunions are accompanied by a cacophony of calls, gestures, expressions and physical contact. The extent to which our shared ancestry with chimpanzees indicates continuity in emotional states remains a contentious issue that reverberates today within the context of **animal rights** and **ethics**.

Charles Darwin was a scientific navigator mapping novel insights into natural history. Although best known for developing ideas about mechanisms of evolutionary change, his prescience was truly amazing: he sought to alleviate pain and suffering in animals, but recognized that animal experimentation was critical for scientific progress; he systematically recorded animal behaviour among both domestic and captive exotic animals in order to obtain insights into biological principles transcending taxa; he recognized that reproductive deficiencies in captivity could arise from physiological as well as behavioural problems; he understood that **inbreeding** could have negative consequences for reproductive success and that mongrels were often healthier than pure-breeds; he struggled with the dilemma of whether the evolutionary continuity between people and apes was based on quantitative or qualitative differences; and he was a brilliant scientist who floated a plethora of ideas, while recognizing that:

False facts are highly injurious to the progress of science ... but false views, if supported by some evidence, do little harm, for every one takes a salutary pleasure in proving their falseness; and when this is done, one path towards error is closed and the road to truth is often at the same time opened.

On 26 April 1882, Charles Robert Darwin was laid to rest in Westminster Abbey, London.

Death

Death is the extinction or cessation of life, and may be used to describe the state of an individual or group of related individuals, e.g. 'death of the dodo'. In the latter sense it is synonymous with **extinction**.

The determination of the point of death in animals is confounded by difficulty in defining the living state, especially in simpler organisms. Within a medical setting death is usually defined in relation to the absence of electrical activity within the **brain**, although **consciousness** may be lost before this, and brain activity can be artificially suppressed temporarily with drugs or as a consequence of hypoxia or hypothermia. At a practical level, the assessment of brain activity is rarely made to determine death in animals, and so the absence of detectable cardiac and respiratory activity is used to determine the point of death. Destruction of the cardiorespiratory centres is often seen as a priority for a rapid death.

For many, death is not a **welfare** issue, but rather the manner of death is. Thus during the **killing** of an animal, e.g. during **slaughter**, welfare may be protected by rendering the animal insensible as rapidly as possible, for example by stunning. None the less, some argue that welfare relates to both the quantity and quality of life, positing that an animal whose life expectancy is artificially reduced has less welfare within it and thus a reduced level of welfare.

Ageing ultimately leads to death, but the evolution of this process and the advantage to fitness conferred by programmed cell death are not fully understood, as it is not a universal process in the animal kingdom (e.g. hydra).

(DSM)

Deceit behaviour

Deceit behaviour is of interest in applied animal behaviour and animal welfare science, mainly because of what it may tell us about the animal's mind: does it show that animals can have intentions? Do deceiving animals intentionally manipulate the *behaviour* of others (first-order intentional deception)? Or do they even understand, and knowingly manipulate, the *beliefs and thoughts* of others as do deceiving humans (second-order

P.161

intentional deception)? Or is deceit behaviour deceptive merely in its effect, not in its intention?

An animal acts 'deceitfully' or 'deceptively' if its behaviour leads another into responding against its interest. The actor benefits from its behaviour, the deceived recipient pays a price. This is demonstrated by the deceptive flashing behaviour of some female fireflies. Female fireflies generally flash to attract conspecific male mates. Females of the genus *Photuris*, however, use two different flashing patterns: one attracts males of their own species, which they will then mate with; the other mimics the flashing pattern of *Photinus* females and hence attracts misguided *Photinus* males, which the *Photuris* females will then eat.

Deceptive behaviour occurs in many kinds of competitive interactions between or within species. Many animal displays are classic models of such interactive behaviours. They have provided much information about the conditions under which dishonest displays, as examples of deceptive behaviour, may evolve. In an exchange of aggressive male threat displays, for example, both participants would benefit from misleading their opponent about their fighting potential by inflating their displays. However, they would

also gain from being able to call their opponent's bluff, that is from being able to accurately assess their opponent's actual fighting potential.

Selection should thus favour individuals that respond only to honest displays. Honest displays are those that can only be produced by an animal that is displaying the truth. For example, when the ability to display is directly related to **fitness**, displays are by necessity honest and deception difficult. A case in point is the roaring display of red deer (*Cervus elaphus*). Roaring uses the same muscles of the thorax as are used in fighting. Roaring is thus an honest display of fighting ability as it cannot be faked by a stag with inferior muscle power. Because the responses of the receivers determine how displays evolve, and receivers are selected for their ability to respond only to honest displays, most displays in competitive signalling systems are honest. None the less, deceptive displays can occur even in evolutionarily stable systems where animals make assessment errors and the deceptions are infrequent enough for receivers to encounter honest displays, at least on average (Johnstone, 1997).

The idea that deceit behaviour may be intentional comes from behavioural observations in the vertebrate taxa, where it tends to be more complex, variable and flexibly deployed than in invertebrates like *Photuris*. A well-studied example is the injury-feigning behaviour of ground-nesting plovers (*Charadrius* spp.). When a fox approaches the nest or young, the plover will start to move away from the fox awkwardly, arching its wings and dragging one or both behind as if broken. The fox, distracted from the nest, may follow the plover, which will maintain the display until the fox is at a safe distance from the nest. The bird will then suddenly take off and fly back to the nest. Field tests have shown that plovers display more vigorously towards 'dangerous' intruders than towards 'nonthreatening' intruders; they will also adjust the direction of their movement depending on the relative positions of the nest, the intruder and themselves so that the intruders are never led closer to the nest.

Some argue that such behavioural flexibility is possible only if the animal has a goal or purpose in mind, which continuously guides its behaviour. The plover thus *intends* to lead the fox away from its nest (Ristau, 1991). However, a problem with interpreting deceptive behaviour as intentional purely on the basis of behavioural flexibility is the mounting evidence that animals can perform highly flexible behaviours on the basis of complex sets of previously learned contingencies.

The most complex and flexible patterns of deceptive animal behaviour have been reported in primates (Byrne and Whiten, 1988). Many primates live in highly structured and long-lived social groups, in which great potential benefits can be derived from manipulating and exploiting group members. This has been proposed as a major factor driving the evolution of intelligence in primates (Humphrey, 1976). Primate deceit behaviour covers a wide range of strategies, such as signalling the presence of non-existent predators (e.g. vervet monkeys, *Cercopithecus aethiops*), using **conspecifics** as 'social tools', thereby misleading a third party (e.g. savannah baboons, *Papio cynocephalus*), and misinforming dominants about the location of desirable food items when foraging in groups (e.g. mangabey monkeys, *Cercocebus torquatus*; chimpanzees, *Pan troglodytes*).

Careful analysis of the data on primate deception shows that, in almost all cases, the possibility cannot be excluded that the primates might have learned to manipulate the behaviour of others to their own ends, without intentionally manipulating the beliefs of others or understanding the mechanism of deception. However, some cases of primate deceit behaviour are hard to explain as learned without understanding, and a strong case has been made for apes intentionally deceiving by manipulating the beliefs of others (Byrne, 1995). Evidence of such second-order intentional deception would show that apes could attribute mental states to others, and had some **theory of mind** ability. Because possessing a theory of mind has been suggested as one of the hallmarks of human-like consciousness, evidence of intentional deception in a given species would lead us to fundamentally reconsider our attitudes towards it.

Research on the mechanisms by which deceptive strategies might arise has recently been expanded to laboratory studies using farm animals and corvids, where learning explanations can be more easily

controlled than in field experiments of primates. Results suggest that, similarly to mangabey monkeys and chimpanzees, ravens (*Corvus corax*) and domestic pigs (*Sus scrofa*) develop potentially deceptive behavioural strategies to avoid exploitation by dominants when foraging together (Bugnyar and Kotrschal, 2002; Held *et al.*, 2002).

Decision making

All animals that live in variable environments need to make decisions about what behaviours to perform, where and when. Normally, animals are able to pursue only one behaviour at a time, even if they have competing strong tendencies to do more than one thing. For example, after a cold winter's night a horse may be motivated to feed, drink and sleep, but how does it decide which to do first? Decision making is the process by which all of the physiological and sensory information available is integrated with an assessment of current environmental threats and opportunities, to permit the animal to choose its next course of action.

The biggest theoretical advance in understanding animal decision making was the view taken by McFarland (1993) that animals evaluate every aspect of their state (although not necessarily by conscious processing of this information) and assess the costs of each course of action using a common cost-function

or 'currency'. If the horse in our example chose first to eat hay, it would benefit from reduced hunger, but would incur the cost of increased thirst. Only by evaluating these costs and benefits on the same scale can the best decision be made. McFarland (1993) argued that evolution has produced animals that make decisions that tend to maximize their fitness (which could, for example, be measured in terms of lifetime reproductive success).

Houston and McNamara (1999) develop these arguments, demonstrating that fitness can be treated as a single unifying currency that encompasses all other biologically relevant currencies. From a practical perspective, however, immediately measurable currencies such as energy or time are evaluated (**see: Economics of behaviour; Motivation**), and usually suffice as a surrogate measure of fitness. By using fitness as a single unifying currency, the value of seemingly disparate activities can be compared. In this way, if, at a given moment in time, an animal has a choice between grazing, drinking or engaging in social activity, we can identify which of these behaviours should be conducted by comparing the changes each of them would bring about in the animal's fitness.

If animals really are evaluating all possible courses of action on the basis of a common currency, then their decisions should be self-consistent and rational. Thus, if an animal prefers A to B, and B to C it should also prefer A to C. There is growing interest in evaluating these features of animal choices, as violations can highlight the currencies that are actually used by animals to evaluate alternative options (Bateson, 2004; Houston *et al.*, 2007).

Of course, decision making involves the **brain**, and the economic perspective taken above does not involve itself with the actual neural processes involved. However, recent work examining human patients with specific types of damage to the prefrontal cortex is providing some new insights into the neuroscience of decision making. These patients make very poor short- and long-term decisions that are not generally in their own best interests, although their **intelligence** is unaffected. This work has resulted in a growing appreciation of the role of brain areas such as the amygdala and the ventromedial prefrontal cortex in decision making, in how decisions are linked with emotional processes and how costs and benefits are encoded by neural systems (Bechara and Damasio, 2005).

Barnard (2007) argued forcefully that the decision-making propensities of animals were of crucial importance in animal welfare. He thought that observing the choices that animals made was the only way to make sense of other welfare indicators that on their own 'provide only equivocal evidence about welfare'. Interest in how animal decisions might be related to animal welfare can be traced back to early studies examining the environmental choices of farm animals (**see: Aversion; Preference**) and to more recent work examining demand functions. Finding that decision making is a strongly emotional process only increases its animal welfare relevance.

Deer

A ruminant, ungulate and member of the cervid family. The males of most deer species characteristically lose their antlers and grow them anew each year. Historically the term 'deer' has included other wild animals outside the cervid family, so some care is needed when considering old documents. Terminology for maturity and sex of animals is not always used in the literature consistently. Mature males (of 5 years), usually red deer, are termed 'stags', mature females (over 3 years), usually red deer, are called 'hinds', while males of smaller deer species are usually 'bucks' and the females 'does'; newborns are 'calves'.

The deer has evolved as a forest animal, and has since prehistory been an animal preyed upon by humans. The deer is, however, not a domesticated animal, or at least its domestication has been so recent as to be unlikely to have affected its behavioural and other needs for good welfare, in comparison with traditional domesticated species. Its long flight distance, agility, speed and social behaviour have made it

P.163

unsuitable for **domestication**. It is an animal that is captive, however: in farms, parkland, zoos and research institutes (see Fig. D.1).

In Europe, and indeed worldwide, farmed deer are most frequently red deer (*Cervus elaphus*), but there are also significant numbers of farmed reindeer (*Rangifer tarandus*) and fallow deer (*Dama dama*), and smaller numbers of others: sika (*Cervus nippon*), shital (*Axis axis*), wapiti (*Cervus canadensis*) and white-tailed deer (*Odocoileus virginianus*). Perhaps as a result of this, scientific research has tended to be most commonly reported on the red deer. Most deer species are social animals, forming single-sex groups. In the male groups, levels of **testosterone** and aggression increase prior to the rutting season, in the early autumn. These aggressive sparring contests prepare the males for (in the case of red deer) the defence of territories - these being areas occupied by the hinds. Fights between stags are common. A resident stag defends his own territory and harem against invaders, but also frequently reasserts the border with his neighbours and tries to increase the numbers in his harem. This is expensive energetically, and the males can lose up to 30% of their bodyweight during the rut, and up to 80% of the accumulated reserves of fat. This loss is through a combination of the increased energy expenditure and a reduction in the time available to spend feeding.

Calving is usually in the late spring, and immediately prior to this the females will seek a hidden, isolated site. Following **parturition** the calf will normally stand within 30 min, and start to suckle within 40 min. Within a week the calf will be able to run with the herd. Calves are totally reliant on milk as a food source for the first 30 days of life. Suckling usually continues until the onset of winter, and may continue

until the following summer in non-gestating females, but the frequency and duration of suckling bouts decreases over the lactation period. Common diseases of deer include tuberculosis, malignant catarrhal fever and yersiniosis; the most important parasite, both clinically and because of its effect on production parameters, is the lungworm *Dictyocaulus viviparus*.

Farming of deer is usually extensive, involving grazing with supplementary feed as conditions require, though intensive systems for young stock are becoming more frequent. Their meat is a high-value product, with lower levels of fat and a higher meat:bone ratio than many other commercial meats, and their production is perceived by the public to be good in terms of animal welfare. There may be overwintering of animals, especially in cold, wet climates to protect the animals, to preserve the quality of the pasture and to better control management. This can lead to problems of pica and aggression, leading to increased skin damage, though the first can be ameliorated by providing browse and the second by grouping according to size. Calves are usually housed over the winter, as they have less fat stored to enable them to survive than the adults.

Fig. D.1. Captive deer in a research facility (image courtesy of M. Ots).

It is common farm management practice to remove the antlers before the rutting season. The antlers begin to develop at puberty, and each year in the spring. They have a covering, the velvet, that is vasculated and innervated. Harvesting of this velvet, for the preparation of oriental medicines, takes place in some systems (but is illegal in some countries) and is presumably painful while in this innervated state. Anaesthetics are recommended for this procedure, although the choice of short-acting drugs can leave some animals unprotected. By the end of September in the northern hemisphere, growth of the antlers ceases, the blood vessels constrict and the velvet peels away. The deer assist this process by rubbing the antlers against rough bark and browsing. The exposed hard antlers are retained during the

rut, but drop off naturally in the early spring. Antler growth can be prevented by disbudding or **castration**. Reproduction is managed on-farm by introducing single stags to groups of hinds, and it is quite common for farms to operate with single stags. Timing of mating is arranged to ensure calving is in spring, as this gives the calves more time to put on weight during the time of highest forage availability, and it also reduces the likelihood of bacterial infection. Early calving can be achieved by improving the nutrition of the females; heavier females have higher conception rates and reach puberty earlier. Overfeeding should, however, be avoided.

Deer are a popular **game animal**, mainly through stalking, tracking and shooting, but also by **hunting** with dogs. It has been argued that the last method was the most stress-free method of culling red deer (to prevent populations exceeding the carrying capacity of a habitat), but this has been disproved, and there is good evidence that the best method of culling or slaughter from a **welfare** perspective is stalking. Hunting with bows is a popular recreation activity in some countries (including the USA), though is illegal in others (including the UK). The welfare problems caused by inaccurate shooting by bow, leaving the deer to escape wounded, have been reported, including pain, ultimately lethal wounding, increased likelihood of predation and septicaemia. Such cases may be as high as nearly 50% of those shot, greater than those reported for rifle shooting. This may be a particular problem for less well-regarded trophy animals such as females, or those with less spectacular antlers, which may not be thought worth following and despatching. Shot animals may survive for days.

On-farm **slaughter** of animals, whether by shooting or in a mobile slaughter facility, is much preferred to their transport to abattoirs that might be some distance away, as facilities suitable for their slaughter are infrequent and not necessarily

P.164

near to the site of production. **Transport** of deer is a welfare problem, as they are not as used to human contact as more domesticated species. **Stress** is induced not just from the journey but also through handling, loading and unloading. Capture myopathy is a common outcome during the transport of deer and during poor handling, indicating damage and presumably pain to the animal, but also results in an impairment in the quality of the meat. There is evidence that this can be ameliorated by the injection of drugs, though administration is itself a problem as a stress-inducing event.

The stress resulting from handling can be reduced by handling in low-light conditions, although this might compromise the safety of the animals and their handlers. It has been suggested that portable handling facilities, designed specifically for the purpose of deer handling, would improve the efficiency of handling procedures and the welfare of both the deer and the handlers. Deer can become aggressive towards handlers, particularly stags during the rutting season, hinds during calving and animals that have been singled out from their group. Young animals and those unfamiliar with either the handler or the handling procedure are more likely to panic. Signs of aggression include flattened-back ears, grinding of teeth, a fixed stare and snorting.

Deer commonly feed on mixed grazed/browsed fodder, and their digestion is similar to other ruminants. However, their basal metabolic requirement is high and they need more energy proportional to their body weight than, for example, sheep. However, a ration high in concentrates, particularly processed grains, can cause acidosis, while high levels of fibrous material can cause ruminal and omasal impaction. Dominant animals are particularly at risk of the former because of their successful competition for access to feed. The feeding pattern of deer is seasonal, with increased voluntary feed intakes leading to greater growth and extensive fat deposition during the spring and summer, supplying them with resources to survive winter periods when feed is in short supply.

Deer can compensate for poor-quality forage by increasing intakes. The stocking rate can have a significant effect on intakes from grazing, with high densities in areas of limited good pasture being associated with reduced body weights compromising their **health** and welfare through the winter. This is

commonly used as an argument for the **culling** of wild deer populations, as well as more managed populations in parkland. It is recommended to supply supplementary feed during the winter, with wet winters being particularly deleterious in terms of body weight loss.

It is common in Europe and North America for wild deer to be offered supplementary feed in the winter, to ensure a viable population for hunting and to reduce damage to the environment through overbrowsing and grazing of the available forage. There are several problems with this, not least of which is that the deer can become reliant on the supplementary feeding, reduce their normal foraging behaviour (on occasion actually to zero) and therefore actually lose weight and condition. Other problems include unequal access to feed, with dominant stags benefiting most and subordinate animals least, and increases in the risk of infections and parasite load from abnormal concentrations of animals in a small space at the feeding stations.

The consideration of the welfare of deer is not restricted only to that arising from farming systems or hunting. Wild deer have been shown to flee from areas used for leisure purposes, such as orienteering, and the energetic costs of this flight might be considerable. The disturbance by the public during visits to parks housing deer is thought to be problematic, and deer show little habituation to such disturbance, although there is conflicting evidence regarding this. Increasing time spent in vigilance behaviour has been found to be at the expense of feeding in the behavioural budget of deer, so disturbance may have an impact on production parameters. Occasions of high mortality of both red and fallow deer in two parks in the UK have been attributed to cumulative stress in the population from visitors (which includes not only the effects of humans alone but also, and more significantly, those of humans with their dogs).

In addition to stress there are direct effects on injury and mortality from disturbance, running into fences, damage from attack by dogs and accidents with motor vehicles. Visitor disturbance is thought to be the reason behind high rates of breeding problems observed in deer. This may result partly from the disturbance of stags, affecting their sexual activity, but is particularly reflected in high rates of calf mortality. This is thought to be due to the abandonment of calves by their mothers following disturbance causing a reduction in suckling behaviour and, perhaps more importantly, reducing their opportunity to form a bond with their calves. This is thought to be at least partly because of the difficulty in finding suitable sites in the restricted areas of parks to conceal calves in the first day of life, which allows bonding and suckling to take place uninterrupted and in security.

Pacing along boundary fences by deer at calving time has been observed to increase, and is thought to be either an expression of effort to find a suitable site or frustration behaviour at not being able to do so, or even to relieve the discomfort of approaching parturition (although overall activity does increase at this time, this is surpassed by pacing itself). This pacing behaviour is more intense when humans are visible and in close proximity. Advantageous ground cover that could offer hinds the choice of such a site, isolated from conspecifics, includes areas of tall plants and heather, though hinds did not choose woodland when offered the opportunity in one study. It was presumed that this was because the deer preferred cover that gave them a view of the surrounding territory. Such a consideration is also, of course, appropriate in other deer-keeping contexts, such as under farming, hunting or other captive management systems. In deer farms for example, the deer typically graze grassland without the provision of such cover.

Assessment of the health and welfare of deer in the wild in particular, but also in managed populations, should be undertaken as non-invasively as possible. Monitoring methods, such as observation of normal and abnormal behaviour, and the analysis of faeces, hair and saliva remaining on grazed pasture rather than sampling of blood, for example, are preferable. Wild non-native deer, such as the sika, muntjac (*Muntiacus reevesi*) and Chinese water deer (*Hydropotes inermis*) in the UK, may have their own welfare problems, including the large, and increasing, numbers involved in traffic accidents. These deer populations are the result of escapes and deliberate

P.165

releases from animal collections, mostly from the last century (**see: Exotic species invasion**). Despite their apparent success in an alien environment, they may face environmental stresses, including exposure to infections, to which they are not well adapted. They may also be treated with less sympathy by the human population than native deer, particularly when causing damage while trespassing in gardens. They are considered responsible for the destruction of plants of conservation value and cultivated crops, particularly the tops of root crops and saplings, through grazing and trampling.

Defecation

Defecation is the act of eliminating solid or semi-solid faecal waste through the anus. Material that has been eaten but cannot be digested is stored temporarily in the rectum. The need to eliminate this material occurs when stretch receptors in the wall of the rectum are stimulated as a consequence of an increase in the volume of material. Relaxation of the anal sphincters allows the material to exit the body. This usually occurs daily and may be under voluntary or involuntary control. Loss of control may occur as a consequence of psychological (e.g. fear response) or physiological stress (e.g. disease). Defecatory behaviour and the quality of faeces can be used in the assessment of animal **welfare**.

Dehorning

Livestock are dehorned to minimize injury to other stock and to stockpersons, and to reduce carcass and hide damage. Dehorning or disbudding (the term usually used when the procedure is conducted on very young animals) is mainly conducted on cattle, although it may also be performed on goats. If conducted correctly, dehorning means that the animal will not develop horns. Dehorning is different from 'horn tipping' or amputation of part of the hard horn, a procedure that is sometimes conducted on adult animals. Horn tipping is much less of a welfare issue than dehorning because it does not normally lead to damage of innervated tissue, although animals must still be restrained for the procedure to be conducted safely (**see: Handling**).

Mature male deer may have their antlers removed for ease of handling prior to transportation or to harvest velvet, but the procedure is different from dehorning in that the antlers will normally grow again the following year. Velvet antler removal is the surgical amputation (by a saw or embryotomy wire) of living, vascularized and innervated tissue, and is banned in some countries. Antler growth can be prevented by the application of a rubber elastrator ring to the developing pedicle, although the technique appears more reliable in fallow than red deer. Behavioural changes indicate that the procedure may cause

some discomfort and/or pain. Antler growth can also be prevented by surgical removal of the pedicle with a disbudding iron, as used on cattle, although there are reports that it is not always effective.

Horns grow from a specialized area of the skin (the corium or 'horn bud') that unites with the cornual process of the skull. The corium produces keratin that forms the outer shell of the horn. The age at which the corium and cornual process join varies with breed/genotype, with reports of it occurring at 7 days of age and at 2 months of age. Evidently, destruction of the corium when it is still 'free-floating' is much simpler, results in a smaller wound and is, therefore, likely to cause less **pain** and **stress** to the animal (see Fig. D.2). Once the corium attaches to the skull, the horn core becomes a bony extension of the skull and the hollow centre of the core opens into the frontal sinuses of the skull. Thus, dehorning at this stage can result in open sinuses, making animals vulnerable to sinus infection and **fly strike** (flies laying eggs in the wound, which leads to larvae living in and feeding on the tissue).

The age at which dehorning/disbudding can be conducted, whether it can be performed by the farmer or a veterinarian and the requirement for **anaesthesia/analgesia** are all legally dependent upon the species and country in which it is performed. Given the way in which the horn develops, dehorning should be conducted at as young an age as possible. Not only does this minimize the extent of tissue damage and, hence, lead to less blood loss and more rapid healing, but also the animals are more easily handled and restrained, which results in reduced stress in them. Animals should be dehorned at a time of year that avoids wet weather and high fly/insect numbers, as this reduces irritation and potential for infection. If flies are a problem then repellents can be applied around the wound, but not on it. High standards of hygiene are also important in avoiding **sepsis**.

There are several dehorning methods that are commonly used, and which one is used tends to depend upon the extent

P.166

to which the horn is developed. All methods of dehorning involve the firm restraint of the animals and produce varying degrees of tissue damage. At a very young age (less than 7 days) caustic chemicals applied to the horn bud of calves will generally destroy it, but there is the risk that the chemicals can get into the eyes, especially if applied during wet weather. Hot iron dehorning/disbudding (also called cautery or thermal dehorning) is best suited for calves up to about 8 weeks of age (see Fig. D.3). A circular iron is heated by fire, liquid petroleum gas, butane or electricity until it is red hot and applied firmly over the horn bud. The iron is rolled over the horn bud several times to ensure that all of the horn-forming tissue around the bud is destroyed. In due course the horn bud drops off. This and the caustic chemical method have the advantages that there is no blood loss and no wound, and so can be performed at any time of the year.

The other commonly used techniques involve amputation of the horn or horn bud and, in all cases, to prevent regrowth a ring of skin at least 1 cm wide must be removed with the horn bud. For young calves (up to about 4 months of age) a curved dehorning knife can be used to slice off the horn level with the skull. For older calves (up to 12 months of age) the most commonly used devices are cup (see Fig. D.4) or scoop dehorning devices (see Fig. D.5). Both devices have cutting blades that amputate the horn bud adjacent to the skin and also remove some of the underlying tissue and bone.

Excessive bleeding is a major concern when older, larger cattle are dehorned and there are reports of deaths from exsanguination. Research on cattle, investigating behavioural and plasma cortisol changes, indicates that cauterisation dehorning and dehorning by amputation are painful and stressful procedures, and that the pain and stress can be alleviated by the use of local anaesthetics and/or systemic analgesics. Dehorning 5-6-month-old calves by amputation without anaesthesia or analgesia causes plasma cortisol levels to peak at 0.5 µg/dl at 1 h post-amputation, then to decline rapidly to plateau values maintained between 1.5 and 3 h post-amputation, returning to pre-amputation levels by about 6 h post-dehorning.

In cattle, horn development is typically classified into three phenotypic groups: (i) horned animals, with fully developed horns attached to the frontal bones, although horn size and shape may vary considerably;

(ii) polled or hornless animals, in which the corneus appendages are totally absent; and (iii) scurred animals in which there are incomplete horns that are not attached to the frontal bones.

Fig. D.3. Hot iron dehorning (reproduced with the permission of New South Wales Department of Primary Industries, Australia).

Thus, there is an alternative to dehorning; the selective breeding of polled animals. Although the exact gene or genes for horned, scurred and polled status have not been identified, it has been determined that the polled gene(s) is dominant/epistatic to that for horned. A third locus, the African horn

P.167

locus, has been postulated, which is epistatic to the polled locus. It is possible that the scurred and African horn factors are different alleles at the same locus. Linked genetic markers for the poll gene(s) have been identified, tested and shown to be accurate (about 95%) in some *Bos taurus* breeds. However, the inheritance of the genes is still poorly understood in *Bos indicus* cattle, and research is being conducted to discover genetic markers related to horn status. There is evidence indicating that there are no differences in production traits between polled and horned cattle in a number of breeds and crossbreeds.

Denervating

Denervating or local **anaesthesia** is applied for a variety of reasons, some more supportive of **welfare** than others. The primary reason for local anaesthesia is to reduce the pain of minor surgical procedures, such as **dehorning** or wound suturing, or to produce regional blocks, for example prior to a rumenotomy. Another use is in diagnosis. Blocking a nerve such as the posterior digital nerve in a lame horse will allow the veterinarian to determine the location of the lesion that is producing **lameness**. Similarly temporary blocking of the infraorbital nerve with lidocaine can be used to determine whether neurectomy could possibly be useful in equine **head shaking**. Head shaking is a relatively common problem of horses and can render the horse unrideable. It is usually a response to pain or discomfort somewhere in the head or upper cervical region. Another trigger can be bright sunshine, i.e. a photic reaction. The antihistaminic cyproheptadine has been more successful than neurectomy as a treatment of head shakers.

Chemical denervating of the caudal nerves, usually with alcohol, is used to keep the tail limp for Western pleasure classes. In such classes the ideal horse is one that can be used for recreation and not working cattle, and therefore should not shy and should be very obedient. When cued to jog (trot) or to lope (canter) it should move very slowly, but it should stop abruptly on command. It should keep its head below the level of the withers. The horse is judged on quietness, and if it lashes (swishes) its tail it will be penalized. Fortunately, electromyography can be used to determine whether the tail is innervated or not. Chemical restraint has also been used to produce both a lowered head and an inactive tail. Blood samples to be tested for drugs are taken from horses in major shows, and nowadays even long-acting phenothiazine tranquillizers, such as fluphenazine, can be detected (**see: Neurectomy** for surgical denervation).

Deontology

Most ethical theories are said to fall into either consequential or deontological standpoints, although in practice a combination of both is usually operative. Utilitarian theories are consequentialist insofar as good actions are assessed according to the beneficial consequences that accrue from them. In general, utilitarian theories are primarily concerned with raising the quality of lives - a goal that is shared by every ethically informed animal owner, veterinarian, doctor, nurse and biomedical researcher. Yet while considerations of utility provide important guidelines in practical ethics, many philosophers and ethicists have argued that **utilitarianism** restricts attention to the maximization of benefit and cannot provide a complete account of moral philosophy.

One of the key alternatives to utilitarianism is deontology, which is derived from the Greek term *deon* meaning 'absolute duty'. Some deontologists speak of an absolute duty to follow divine commands, whereas others attribute the source of duty to natural law. Deontologists speak of duties to be fulfilled regardless of the consequences, and these will include telling the truth, keeping promises, respecting the autonomy of others, never treating people as means to others' goals and treating others as you would want to be treated yourself. Problems in medical practice are said to occur when a conflict of duty arises. Consider the conflicting imperatives to: (i) do everything possible to combat illness and preserve life; and (ii) show respect for a patient's right to self-determination, which may include an express wish to forgo certain forms of life-sustaining therapy. If both duties are to be accepted as absolute then the conflict cannot be resolved.

Deontology is largely associated with the rule formalism of **Immanuel Kant** (1724-1804), who maintained that appeals to utility cannot account for some of our most strongly held moral beliefs. Whereas the utilitarians, **Jeremy Bentham** (1748-1832) and John Stuart Mill (1806-1873), adopted a consequentialist theory, seeking the maximization of happiness (which they equated with 'good'), Kant insisted that consequences do not make an action right or wrong. Rather, it is the principle upon which the agent acts that is the morally significant factor. His emphasis on the principles that underpin moral actions has some obvious advantages. Very often we carry out an action with the best intentions, only to see the outcome frustrated by unintended circumstances because, once initiated, the outcome of an action may be influenced by a network of causes and effects beyond our control. A veterinarian may administer a drug with the best intentions and yet, because of some unforeseen circumstances - e.g. an undiscovered side effect - the animal may suffer greatly or die. The consequences are bad, but unintended. Do we now conclude that the veterinarian acted immorally?

Consider a case from the other side: a careless and irresponsible veterinarian misdiagnoses an illness or prescribes the wrong medication, but the ill effects are abrogated by a series of accidents; the animal expels the medication and manages to recover. The result is beneficial, but the veterinarian's action is morally questionable. It is unjust to limit the moral assessment of certain actions to the consequences;

common sense and justice inform us that the agent's motives and intentions should be included in the assessment.

According to Kant's deontology an act is moral only if it springs from a 'good will': that is, an act arising out of a rationally based sense of duty, as opposed to acting out of inclination. Duty, maintains Kant, is governed by respect for the moral law; an act is good not because we enjoy it, or because it brings happiness or pleasure or relieves suffering, but because it is performed out of respect for the moral law. This is expressed in Kant's famous categorical imperative: 'I ought never to act except in such a way that I can also will that my maxim becomes a universal law'. This formal statement is predicated on the moral equality of all, and expresses the view that the measure of right action is that it can be universalized

P.168

without violating the equality of all human beings. It implies treating others as ends, not as means, and respecting the autonomy of others.

Although criticized for excessive formality, Kant's deontology has practical application. Consider a researcher who intends to carry out experiments with a certain drug on companion animals. The predicted outcome of the research is that it would bring considerable benefit, but there is a risk of adverse side effects for the animals in the experiment. Were the owners of these animals informed of the risks they would probably withhold consent. The researcher lies, saying that no risk is involved. The researcher can be said to be acting on the principle that 'whenever your research is imperilled by the reluctance of subjects to participate in it, it is permissible to lie'. This maxim cannot be willed as a universal law; if it were it would amount to universally endorsing the making of false promises in the interests of scientific progress, and this would indicate that the very meaning of making promises (truth telling) would be jeopardized. The maxim could not be universalized without self-defeat. It should be stressed that Kant's deontology does not appeal to the consequences of dishonesty, but is designed to show that some principles cannot be universalized without involving the author in a contradiction.

Kant's rule deontology has been criticized for excessive formality and the difficulties it faces when providing a guide for conduct when facing a conflict of duties. Nevertheless, his insistence that to be moral we should require that individuals are treated as 'ends', not as 'means', is the basis of our respect for autonomy, the doctrine of informed consent and a resistance to paternalistic exercise of authority in professional conduct.

Depression

In relation to humans, depression describes a condition of persistent negative mood, and as a clinical disorder is the most commonly diagnosed psychiatric illness in modern Western society. It encompasses a number of more specific conditions including major depressive illness, dysthymia, bipolar disorder and seasonal affective disorder. In humans, to a greater or lesser extent, each of these diseases is characterized by feelings of **apathy**, hopelessness, helplessness, inability to experience pleasure and worthlessness and, in severe cases, can result in suicide. Signs and symptoms of depression include sleep disturbances, increase in fatigue, changes in appetite, social withdrawal and a reduced ability to

concentrate. Various theories regarding the development of depression have been proposed, but no single explanation regarding its underlying aetiology is accepted. There is also still debate regarding the distinctiveness between depression and other negative affective disorders such as **anxiety**, due to the overlap in many of the diagnostic criteria and presenting symptoms between the different conditions. Given the subjective nature of the properties of depression when applied to humans, analogy with the term when applied to animals should be with caution.

Ethological laboratory models of depression for the screening of antidepressant drugs are often based on the induction of suppressed behaviour through manipulation of social **stressors**, e.g. through social isolation and changes in social hierarchy or the use of physical stressors that may be chronic or acute, such as those based on the induction of **learned helplessness**, the tail suspension test (the animal is suspended by its tail with sticky tape for 6 min) and the forced swim test (the animal is forced to swim repeatedly in a bath for 15 min and the amount of time spent immobile recorded). The effect of these drugs on spontaneous behaviour, such as **exploratory behaviour** in either an **open-field test** or **elevated plus-maze**, may also be used as part of the screening process, since these drugs are expected to increase such activity.

In animals, the term depression is usually applied to situations where the normal behaviour of the individual is altered such that they appear less active and exhibit reduced interaction with their environment, **conspecifics** and, especially in the case of **companion animals**, possibly with human members of their social group. This behavioural depression has a physiological basis in situations of illness through the production of **cytokines**, and has been studied in conjunction with other effects of these mediators, such as the suppression of appetite.

Behavioural depression as a result of negative affect is more difficult to determine in animals, as mood cannot be assessed through the articulation of feelings. However, certain theories regarding the evolution and development of depression in humans - neuroanatomical correlates combined with data on neurotransmitter levels (especially **serotonin**) associated with depressive conditions - make speculation in this area of interest to those concerned with animal **welfare**. One of the theories regarding the evolutionary value of depression speculates that a depressed mood may be linked to an increased withdrawal from situations of conflict and a yielding of status in a dyad (**see: Hierarchy**), which helps to reduce the risk of exclusion from a **social group** following conflict.

Elevated mood is hypothesized to be associated with the ability to hold a resource, depressed mood with the surrendering of the resource, within conscious individuals (**see: Consciousness**). Both could potentially occur as acute or chronic events, and the function of depression for the individual would thus be the ability to remove oneself from a ritualized conflict without sustaining life-threatening injury. As social groups depend on **cooperation**, individuals that yield in these situations and inhibit their behaviour are less likely to provoke further agonistic interaction (**see: Agonistic behaviour**), and so could remain within the population without further compromising their **fitness**.

The neurotransmitter alterations that appear to correlate with the unsuccessful outcome of a conflict situation seem to bear some similarities to the alterations described in individuals experiencing depression, which adds some support to this theory. Evidence for a genetic component to depressive illness in people may add further support for this trait being part of the normal range of human emotional processes. However, it may be that modern circumstances provoke an extreme or abnormal level of response that results in a less adaptive clinical condition. Postulated proximate triggers (**see: Tinbergen's four questions**) for the condition include loss

P.169

of status, abilities or interpersonal conflict, and the impact of these may be exacerbated when they have a perceived lack of **controllability**.

Arguments based on evolutionary continuity may provide a theoretical basis to suggest that depression might have parallels in animal species with highly evolved **social behaviour** and systems. This may be reinforced by new experimental approaches to the assessment of the subjective states of animals, such as **cognitive bias** tests and, although we cannot know the subjective experience of another, the **precautionary principle** may be applied to protect their welfare as we understand more about the biology of the condition.

Descartes, René

René Descartes (1596-1650), the professed 'father of modern philosophy and modern natural science', was a philosopher and mathematician who was also a leading exponent of the mechanistic view that emerged after the Middle Ages. As is commonly imputed to Descartes by many scholars, he argued that human beings alone were members of the moral community because they alone were 'thinking beings,' i.e. beings who possessed the mental faculty of reason, had propositional language, who could reflect abstractly and who possessed the 'faculty of judgment'. Animals were conceived as nothing more than nature's complex automata. He considered them biological robots, no different in kind from a sophisticated clock. Under this interpretation, Descartes held that animals were incapable of conscious mental states. They 'do not perform any action which indicates that they can think', he argued. Here, since animals are but unconscious 'wind-up' material objects, treating them as mere objects of use should raise no ethical concerns whatsoever.

Descartes' view on animals received dissent from a notable contemporary, Pierre Gassendi, a priest and logician, who insisted that we ought to focus on certain other mental capacities of animals besides their lack of rationality. Gassendi called attention to animals' perceptive abilities and their ability to suffer. He also argued that our ability to reason makes it incumbent upon us to be humane and to exercise

compassion towards animals. Gassendi argued that 'There is no pretence in saying that any right has been granted to us by [the moral law] to kill any of those animals which are not destructive or pernicious to the human race'.

Interestingly, Descartes did not deny that animals were capable of all 'sensation'. They possessed **memory**, perception, fear, joy and hunger. However, he denied that these experiences are conscious in the relevant sense, i.e. that there is something it feels like for an animal to experience these sensations. He held that animals were limited in their hardwiring. For Descartes, animals 'sense' their environments just like a thermometer 'apprehends' the temperature and registers it. By analogy, since a thermometer is not conscious, attributing intentionality to it, i.e. to suggest that it can 'feel or experience cold or hot' is **anthropomorphism**, bordering on preposterous.

Desensitization - systematic

Systematic desensitization is a commonly used behavioural modification technique for the alleviation of behaviour problems in animals caused by inappropriate **arousal**. Typical patients are animals that become inappropriately aroused when in the presence of a particular stimulus or situation - for example, fear-related behaviour in the presence of fireworks, aggression towards other dogs and overexcitement towards visitors.

The process in animals is an adaptation of a psychotherapy technique originally developed by Wolpe (see Wolpe and Lazarus, 1969), and is based on the concepts of **habituation** or conditioning relaxation in response to the problem situation. The animal is exposed in a controlled situation to low levels of the arousing stimulus according to an increasing gradient, and rewarded when it remains relaxed or shows an appropriate response. An increase in the level of the stimulus is not made until the animal reliably fails to react to the previous level. In this way the technique aims to raise the threshold for a response to this particular stimulus. The process is usually speeded up by rewarding the animal for remaining relaxed (respondent **counter-conditioning**) or training it to perform a different response in the presence of the arousing stimulus (operant counter-conditioning).

The first stage is to identify the arousing situations. These are then broken down into the relevant component stimuli that might contribute to the animal's response. These might include the sight of the object, its smell, its sound or the location (taste or touch may also be involved). It is particularly important to do this if the arousing situation is complex, such as a visit to the veterinary clinic. Then the therapist and pet owner should work out a schedule for exposing the animal to very low levels of these stimuli. Intensity is controlled in a number of ways, e.g. through controlling distance, volume, etc., depending on the stimulus (see Table D.1). Single stimuli may be presented to the animal and, once a reliable level of desensitization to these has occurred, multiple stimuli may be presented together (usually at an initially lower intensity than the individual stimuli) until the animal is desensitized to the

P.170

whole scenario. The type of stimulus and the levels by which it is introduced make up the stimulus gradient. The stimulus gradient and rate of progress depend on the situation that is provoking the arousal.

Table D.1. Commonly used methods to control the intensity of a stimulus during desensitization programmes (stimulus gradient).

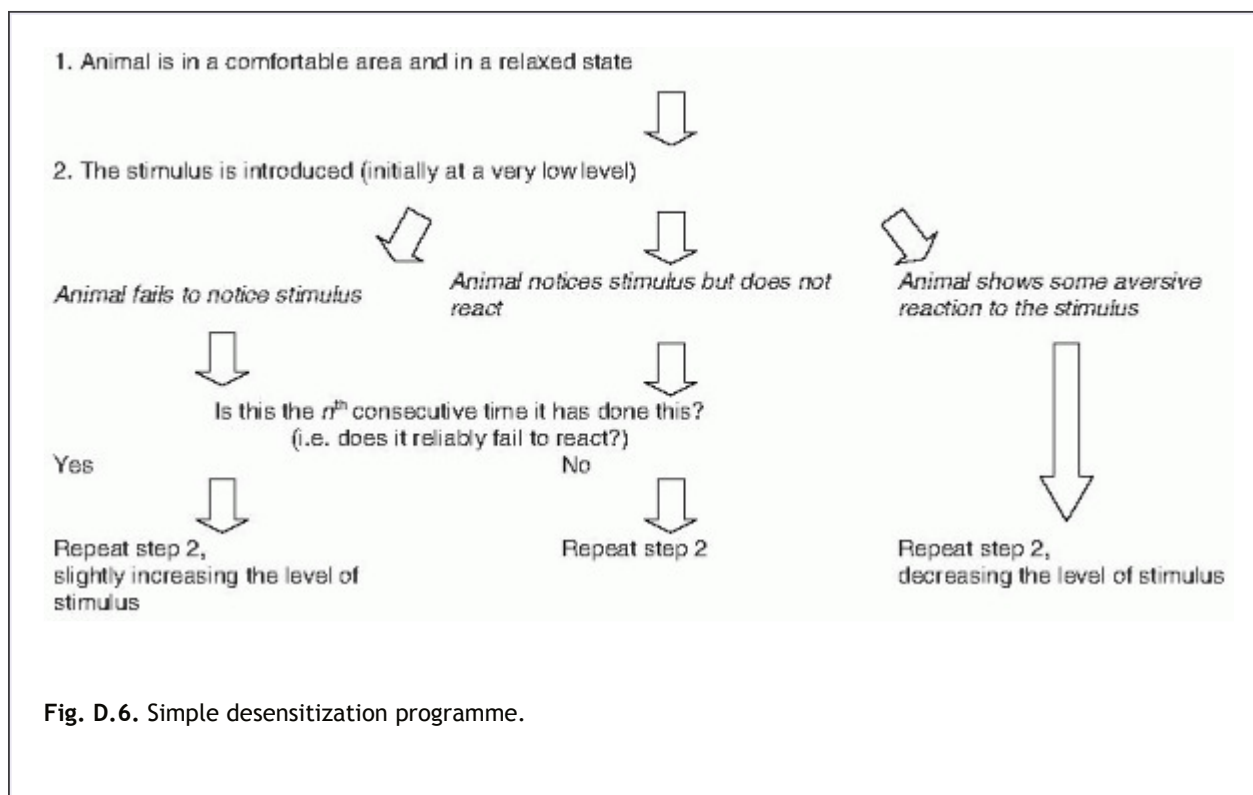

Stimulus quality	Possible scenario useful for:	
Distance	Exposure to other, controlled objects at decreasing proximity	Over-arousal towards animate and inanimate objects, e.g. other people, animals, vehicles
Volume	Play a recording of the noise at increasing levels	Fear-related behaviour to loud noises, e.g. fireworks, hair clippers
Visual similarity	Exposure to similar situations involving similar objects	Over-arousal in specific situations (may involve animate or inanimate objects), e.g. visiting the veterinarian, car journeys

A combination of methods for controlling intensity may be used within a given desensitization programme; for example, desensitization to car journeys may begin with approaching the car (distance) and sitting in another, novel, car (similarity).

Once the stimuli have been ordered from the least arousing to most arousing, the desensitization programme can begin. Figure D.6 lists the basic process.

If the animal begins to show signs of inappropriate arousal to the stimulus, the exposure should cease and the animal should then be distracted and ignored until it calms down. The stimulus should then be reintroduced at lower levels than the previous exposure. It often helps if sessions are relatively short and frequent and cease when the animal is relaxed in the presence of the stimulus. As desensitization is a learning process the subject is prone to forgetting, and so new sessions should start with the stimulus presented a lower level than that at which the previous session finished and, once the goal has been achieved, this should be regularly reinforced by exposure to the original arousing stimulus on an intermittent basis. It is also useful occasionally to expose the animal to lower levels of the stimulus to which it reliably fails to react during the training process, so exposure is less predictable; however, exposure to the natural stimulus during training should be avoided if possible, to prevent disruption to the learning process. In an ideal situation both the stimulus and the animal should be under careful control during the rehabilitation process.

Despotic species

Despotic species have a steep dominance hierarchy, in which only one or a few individuals display **dominance** while all others show **submissiveness**. Displays of **aggression** are rare but fierce when they do occur, and resource access is biased towards high-ranking individuals. This affects the social **grouping** of the animals and a clear spatial structure emerges, with high-ranking individuals in the central area and subordinates at the periphery. With this type of dominance hierarchy females can attain higher dominance rankings than males, and females tend to select only high-ranking males as mates.

(LMD)

Development of behaviour

The development of behaviour can be considered in both a proximate and an ultimate sense. In the former it relates to **ontogeny**, and in the latter to **phylogeny**. In either case, variability in the process that facilitates adaptation is an important feature.

This listing focuses on the processes influencing development within the lifetime of the individual (ontogenetic development), the other process being considered the **evolution** of behaviour.

Historically, the nature-nurture debate has featured prominently in the investigation and description of behavioural development, with advocates of the former placing an emphasis on '**instinctive**' behaviour processes and the importance of genetics, to the point of arguing for biological determinism (or preformationism) in the development of some behaviours. While the opposing perspective, epitomized by radical versions of Watson's **behaviourism**, has suggested that the environment is all-important to development and has placed a greater emphasis on the lability of the process (although it is important to recognize that flexibility does not just come from learning). Needless to say the reality is somewhere in between, with both genetic and environmental factors being essential for normal development and able to effect change.

However, there may be differences between the two in the proportion of the variability seen that can be ascribed to genetic versus environmental factors, and this can be quantified by careful determination of the **heritability** of the trait under consideration. Within the context of behavioural development, such calculations are complicated by the dynamic relationship that exists between the two. The concept of **epigenesis** proposes that the genotype interacts throughout life with the environment to produce a changing phenotype. Both environmental and genetic factors may, however, be important in limiting the variability of responses seen during development; for example, exposure to certain endogenous or exogenous stimuli may start to canalize the response so that it becomes more stimulus-specific. This is sometimes referred to as a shift from a more open to a more closed programme.

Although development is a continuous process throughout life, it is not an even process, with genetic and environmental factors influencing the current phenotype throughout life to varying degrees at different times, producing discontinuities in development. For example, **sensitive phases/critical periods** are times of particularly rapid development, when the animal may be prone to learning particular types of association and during which the first exposure to certain environmental stimuli can have a rapid and long-lasting effect (e.g. resulting in **imprinting** and **bonding**).

Even though it is tempting to think of these phases of development as being periods when environmental influences are most important (see the nature-nurture perspective mentioned above), it is important to appreciate that the timing of these developmental phases is regulated by both genetic factors and experience. For example, although general timings may be offered for the socialization phase of a dog as occurring between 3 and 12 weeks of age (Scott and Fuller, 1965), the onset of this and many other developmental processes may be delayed in the absence of appropriate stimulation, and curtailed sooner after a certain level of stimulation. Thus 3-12 weeks may not represent the time span throughout which an individual dog is particularly sensitive to learning about other individuals, but rather the average range for dogs in general (some starting earlier and some later). Therefore, it may be that the timing for a given individual is much shorter, depending on the timing, quality and quantity of stimulation received.

Just as some developmental processes appear to emphasize the role of the environment, others emphasize endogenous factors - for example, maturational changes (e.g. onset of **sexual behaviour**), which depend on the development of the body to a certain degree before they can be expressed functionally. The timing of these, too, depends on a balance between genetic events and environmental influences, e.g. plain of nutrition, presence of members of the opposite sex.

These examples serve to emphasize the important difference between chronological time (days, weeks, months, etc.) and individual developmental time (i.e. stage of development) in the onset of specific developmental processes, and the danger of simple generalizations. Related to the concept of individuals developing according to their own history is the importance of recognizing that development does not represent a process during which an animal progresses towards being a fully functional being, but rather that an animal has different functional stages to its life, each of which is adaptive to normal circumstances, and development represents the process - including transition - from one stage to another. In a given circumstance a given stage of development may be most appropriate. Thus the **neonatal period** maximizes **fitness** by exploiting the maternal resource available at minimal cost.

Given the dual influence of environmental and genetic factors on the developmental process, and the adaptive value of different life stages, there is the potential to select for and exploit differences in the process. Thus broilers have been selected for and managed in a way that exploits the rapid growth phase associated with earlier stages of development. In dogs it has been suggested that they differ from wolves as a result of selection for the retention of juvenile characteristics into adulthood (paedomorphosis), and that different breeds have evolved as a result of selection heterochrony (changes in the relative timing of developmental processes), especially in relation to the development of the hunting sequence, which allows dogs to fulfil different roles more easily (see Coppinger and Coppinger, 2001).

Thus traditional rescue breeds (St Bernard, Pyrenean Mountain dog, etc.) have been selected (either directly or indirectly) for high levels of competence in the location of heterospecifics (an early part of the sequence to appear in puppies, which coincidentally is associated with a high growth rate and so larger adult size), whereas herding sheepdogs have been selected for stalking and chasing without the bite. Since these behaviours develop later, they are not associated with a phase in life with such high growth rate, and so these breeds tend to be smaller and have more adult 'lupine' facial features (see Fig. D.7).

The scientific investigation of the factors that might facilitate, initiate or maintain the development of a given behaviour is methodologically very challenging, not least because the same end point may be reached by different processes in different individuals (equifinality), and interactions

P.172

between different experiences may play an important role in development (e.g. in the balance that occurs between response **generalization** and **discrimination**). Cross-sectional epidemiological studies may be used to reveal factors of potential significance, although association does not indicate causality. For example, it has been found in several cross-sectional studies that horses that develop **weaving** behaviour are often also those with reduced social contact (increased risk odds ratio).

Fig. D.7. Comparison of Border collie (front) and Pyrenean Mountain dog (back) head profiles. Note the more domed head and more rounded features of the larger Pyrenean Mountain dog, which is generally more paedomorphic (puppy-like) in appearance.

However, three plausible explanations are that: (i) horses that weave are generally kept away from other horses because of (unfounded) concern that the unaffected horses may copy the behaviour (i.e. weaving

results in a lack of social contact); (ii) lack of social contact is stressful for horses, and this predisposes them to weaving (i.e. lack of social contact results in weaving); or (iii) the sort of horses that weave are also the sort of horses to have reduced social contact due to some common factor, e.g. breed, use in racing, etc. (i.e. that lack of social contact and weaving both result from some other factor). The latter can be assessed by examining interrelationships with other factors, but this depends on the ability to identify this common factor first. It is possible for all three statements to be true simultaneously because one does not necessarily preclude the other. In an attempt to focus on the role of specific factors, **isolation** experiments have been proposed, in which the effect of depriving the animal of specific stimuli during development is assessed. There are numerous methodological challenges with such work.

First, the level of isolation used is often unrealistic and results in an unnatural level of consistency in the environment, which may have its own effects on behaviour, beyond that which is being studied; it is also important in any study of behavioural development to distinguish between effects that impact on a specific behaviour and more general effects on behaviour (isolation has general effects on emotionality).

Secondly, it may be difficult to determine exactly what the subject is being isolated from, as the perceptual world of other species is different from our own and it may be that certain stimuli can substitute for each other in certain circumstances (whether or not this occurs in normal circumstances remains unknown as a result of the experiment) - thus a negative result does not mean that the given factor is not important. Thirdly, in some experiments it is not possible to distinguish between the post-isolation effect and the treatment effect, i.e. the result is due to the animal's response to release from isolation rather than to the isolation itself.

Finally, there are also problems with interpreting results due to an interaction between the age of subjects, the timing of the treatment, testing and time elapsed between treatment and testing (see Martin and Bateson, 2007). Related to this is the timing of assessment and importance of distinguishing between short-term and long-term, or transient and more permanent, effects. Many animals can compensate for a period of deprivation during development, and may return to normal should circumstances allow at a later date; however, it may also be that short-term disruption can result in long-term effects indirectly: for example, in the absence of exposure to people a dog may be fearful upon first encounter, and the response of the person to this initial encounter could change the long-term developmental pathway. Someone who gives the dog time to investigate and assess the situation may help the dog to overcome its wariness of people and ultimately allow it to become socialized, whereas the individual who insists on handling it like a normally socialized dog is likely to provoke an extreme fear response that reinforces anxiety towards people in future.

These criticisms and others (relating to the analysis and interpretation of results) apply to one of the best-known series of studies into behavioural development, namely the work of Scott and Fuller (1965) on dogs, the conclusions of which have now become almost lore among those working with dogs - despite their questionable validity - being heavily biased towards the deterministic view of behaviour that dominated thinking at that time. Many of the difficulties outlined above are equally applicable to other experimental methods of investigating behavioural development, and serve to emphasize the need for multiple testing and methodologies before firm conclusions about the influence of different factors on development can be made.

DFD meat

DFD stands for dark, firm, dry, and describes the appearance of meat. DFD meat is also referred to as 'dark cutting' and is a meat quality defect resulting from a lack of the normal acidification of meat post-slaughter. Between slaughter of the animal and chilling of the carcass, glycogenolysis occurs in the muscle and, in this process, glycogen is converted to lactic acid. Glycogenolysis decreases the pH of the meat. Good-quality lamb and beef has a final or ultimate pH value close to 5.5, and above a pH of 5.8 the colour of the meat darkens progressively with increasing pH; meat with an ultimate pH of greater than 5.9 is generally classed as DFD meat. The term 'black beef' has been used to describe meat of a neutral pH value (around 7.0), which is the value generally found in the live animal.

Cut DFD meat does not bloom or brighten when exposed to the air, and appears dark coloured because less light is reflected, the presence of deoxymyoglobin and the reducing sugar content affecting colour development. The dry appearance of the meat is thought to be a result of an unusually high water-holding capacity (both raw and cooked), causing the muscle fibres to swell with tightly held water. As a consequence of this water-holding capacity, DFD meat loses little water during storage. The appearance of DFD meat does not appeal to consumers. DFD meat is variably reported as being either more or less tender and juicy than good-quality meat (differences may depend upon the ultimate pH). However, it has a reduced flavour or a noticeable 'off' flavour. The meat has a reduced shelf life and, in particular, does not survive well in vacuum-packaged anaerobic storage due to the absence of glucose as a substrate for bacteria. Instead, the amino acids are used by the bacteria, producing spoilage odours much sooner than would happen with good-quality meat.

This category of meat is important from an animal welfare perspective, as it can be indicative that animals have experienced stress pre-slaughter. In healthy, well-fed cattle, the concentration of muscle glycogen generally ranges between 60 and 120 $\mu\text{mol/g}$, although can be as high as 200 $\mu\text{mol/g}$ in grainfed cattle (see: Feedlot). Rapid glycogen breakdown in living muscle may be triggered by an adrenergic mechanism, a contractile mechanism or a combination of both. These two rapid mechanisms are activated by the sympathetic and somatomotor nervous systems, respectively, and act by increasing the concentrations of cyclic AMP and calcium ions (see: Stress). Additionally, low muscle glycogen can arise through slow depletion, as a result of low energy intake over an extended period.

Cattle DFD meat has been found to be correlated with a number of factors. The incidence is higher in the following situations: (i) in bulls rather than in steers or heifers; (ii) when groups of unfamiliar animals have been mixed; (iii) in oestrous females; (iv) when animals have been food-deprived or had poor-quality

food over an extended period; (v) after long-haul **transport**; and (vi) after cold exposure. Some reduction in glycogen levels pre-slaughter can be accommodated and have no adverse effects on meat quality, but if levels fall below 40-57 $\mu\text{mol/g}$ the ultimate pH will increase. Thus, a combination of factors is more likely to predispose animals to glycogen depletion than a single factor.

Mixing unfamiliar animals can lead to high levels of aggressive interactions, particularly between bulls, and mounting behaviour, which is also seen between oestrous females. Physical activity per se does not necessarily result in glycogen depletion, but rather it is the intensity of activity that determines glycogen levels. Furthermore, mixing induces emotional stress because social relationships and the social hierarchy are disrupted (**see: Hierarchy; Social stress**). Mixing cattle pre-slaughter probably has the most detrimental effect on glycogen loss and should be avoided.

Muscle glycogen levels will, also, evidently be influenced by initial glycogen levels, which may be determined by nutritional history. Feedlot cattle, for example, are less predisposed to producing DFD meat, which can, partially, be attributed to their superior nutritional status and concomitant high muscle glycogen levels. Furthermore, such animals may experience less stress pre-slaughter than cattle coming from pasture, because of increased exposure to and experience of handling and humans.

Glycogenolysis varies between muscle and fibre types; muscles along the back and hind legs appear to be most susceptible; **epinephrine** has a marked glycogenolytic effect on slow-twitch fibres but not on fast-twitch, but the opposite is seen when muscle is given low-frequency stimulation. These differences reveal why mounting activity is closely correlated with DFD meat and also suggests that in situations that are not physically demanding it is the emotional state of an animal that is critical in relation to glycogen loss.

There is some evidence that the character or temperament of cattle affects meat quality and the incidence of DFD meat. The mechanism has not been fully determined, but it may be that animals of different characters also differ in the proportions of muscle fibre types (fast and slow twitch), or that animals with poor temperaments do not cope well with the stressors associated with transportation and slaughter and, therefore, glycogen loss is rapid, or it could be a combination of such factors.

Cold exposure may deplete glycogen through the development of hypothermia, shivering and non-shivering thermogenesis (**see: Cold stress**). Cold exposure can occur during transportation or when animals are washed/hosed prior to slaughter.

Transportation over distances of less than about 400 km probably has little effect on glycogen depletion and ultimate pH, but over much greater distances there may be slight effects. Attempts have been made to attenuate transportation stress using mixtures of sugars and electrolytes provided to the animals on-farm immediately prior to transportation, or while

P.174

in lairage. The results on the effectiveness of such treatments in reducing the incidence of DFD meat are equivocal.

Rest post-transportation potentially allows glyconeogenesis to occur, raising muscle glycogen levels. However, glycogen repletion rates are slow in ruminants (compared with monogastrics), ranging between 0.1 and 1.0 $\mu\text{mol/g/h}$, depending on the extent of glycogen depletion and inanition, and access to feed. To avoid DFD meat, cattle with subcritical levels of muscle glycogen would require in excess of a 48 h rest and recovery period (**see: Lairage**). For bulls there is a clear reduction in DFD meat with short rest periods, and the same may apply to cattle that have been minimally stressed pre-slaughter. There is an indication that short rest periods (less than 12 h) may reduce DFD meat.

(JCP)

Diagnosis

A diagnosis is a decision about the cause of the disease that is affecting an animal. In UK law only a veterinarian can formally make a diagnosis in an animal.

(DBM)

Diarrhoea

Usually refers to loose faeces, but can also be used to describe a very frequent passage of normal stools. 'Looseness' can be anywhere on a spectrum from being a less solid stool to a frank watery excretion due to transudation of fluid from the gut wall into the gut lumen. In some species diarrhoea may even contain mucus due to hyper-stimulation of the mucous glands in the intestinal wall.

(DBM)

Diet selection

Diet selection at its simplest level considers the attainment of nutrients from available foods in order to meet physiological requirements for maintenance, growth and **reproduction**. The study of the concept of diet selection and associated feeding behaviour has interesting applications for the applied animal sciences. Understanding the causal mechanisms underlying diet selection has practical implications for the development of diets or feeding systems that promote animal health, behaviour, production and environmental sustainability. In a natural setting nutrients are obtained from a variable environment, in which sensorily distinct foods vary spatially and temporally in their nutrient quantity and quality. Equally variable is the animal's physiological requirement for nutrients, which change according to life stage, reproductive stage and within the range of normal activity patterns, including the fight or flight response.

The challenge faced by an animal is to select a diet from this varied environment that meets its needs. It is worth noting that diet selection may be less complex for captive and domesticated species, as often a 'balanced' diet proportionate to their requirements is readily provided. However, the animal will still be faced with the same problem of deciding whether to eat, what to eat (if choices are available) and how much to eat. Whether an animal can select a nutritional diet, when given the opportunity, has been the subject of considerable research and debate, given that the wisdom of the body is often called into question when animals and humans fail to select appropriate diets either by the consumption of toxic foodstuffs or the long-term selection of foods that lead to obesity or metabolic conditions.

Models of **optimality** have been used to understand the rules governing diet selection and the adaptive significance of **foraging behaviour** patterns. **Optimal foraging** theory uses a univariate approach to the understanding of feeding behaviour, by predicting that the decisions that animals use to select a diet will maximize their net rate of energy intake (Stephens and Krebs, 1986; Hughes, 1993). Alternative models have examined foraging decisions in relation to the quantities of the three main energy sources within foods, the macronutrients: protein, fat and carbohydrate. This area of research has grown from the premise that the relative proportions of different macronutrients within individual foods influence selection and consumption patterns.

One model, the geometric framework of nutrient balancing, developed by Raubenheimer and Simpson (1997), is based on the idea that the proportions of different foods that are ingested is dependent upon the degree that a particular nutrient intake target can be reached. The intake target is the optimal combination of nutrients that, if ingested, will maximize an individual's performance and minimize post-ingestive processing costs. This latter model also takes into account the fact that animals may not always act to maximize nutrient intake as, in certain situations, trade-offs develop between macronutrients and other dietary requirements, such as sodium.

Selection between different foods is often based on the familiarity of the organoleptic characteristics, i.e. those relating to the flavour, texture and temperature of the food item, as identified by olfaction and

taste perception. Many species are neophobic and will either avoid novel foods completely or ingest them in small quantities. Sensory characteristics do not act in isolation to drive food choice. Signals are received from the gut, the liver, circulating factors and adipose tissue. The **central nervous system** integrates these signals with those from the external environment, which, coupled with prior, learned experience, modify and regulate the animal's **feeding** behaviour.

Post-ingestive **feedback** from the gastrointestinal tract acts to modulate dietary choice. Signals that relate to gastrointestinal tract distension, nutrient feedback and malaise act in association with organoleptic properties to influence the degree that ingestion is initiated, maintained or terminated. Thus the sensory signals generated prior to and following ingestion are the cues that the animal can use to associate with the consequences of eating particular foods (Booth and Thibault, 2000). If food properties remain stable, the organoleptic characteristics will reliably predict the positive or negative consequences of ingesting particular foods. This association has been demonstrated experimentally by pairing a flavour with a nutrient infusion that was administered intragastrically. Favourable post-ingestive consequences increase the acceptance and the ingestion of a food. For example, Villalba and Provenza (2000) investigated whether lambs' intake of wheat straw was guided by organoleptic properties or from feedback from the gastrointestinal tract. Lambs were fed the same source of wheat straw and the simulated post-ingestive consequences were manipulated by either a water or starch intraruminal infusion. Wheat straw was eaten sparingly or avoided when presented to lambs in 5 min tests with or without an intraruminal infusion of water. However, ingestion

P.175

of wheat straw was enhanced, as measured by an increase in intake rate, when ingestion of straw was paired with an intraruminal infusion of starch. The strength of the association ensured that the effect persisted, since Villalba and Provenza (2000) found that the association persisted for 9 days after the starch infusion was removed.

The decision made by the animal to start or terminate a feeding bout over and above other behavioural patterns is dependent upon a multitude of factors. Broadly, these can be classed into external and internal factors. External factors include the aspects within the immediate location such as the presence or absence of appropriate food items, social conspecifics, natural predators and environmental conditions. Internal factors, on the other hand, include influences from physiological processes that act to maintain the internal **homeostasis**. For example, food intake slows as the meal progresses, which may reflect feedback from the gastrointestinal tract.

Internal and external factors are not mutually exclusive - they interact; for instance, free-ranging horses have been observed to cease grazing and seek shelter during the inclement weather conditions of the winter months. This strategy may allow them to conserve energy while the nutrient content of the available forage is low. However, feral horses with low body condition scores have been observed to maintain grazing patterns, even during adverse weather conditions, presumably due to a greater need to replenish body reserves.

Dietary fibre

Dietary fibre describes feed components that are less easily digested. Dietary fibre is digested by microbial enzymes in the rumen of ruminant animals and the hindgut of monogastric animals, but not by enzymes produced by the animals themselves. It is a normal component of the diet of herbivores. Most usually it is obtained from plant-derived material, such as cellulose, hemicellulose, fructans, gums, pectins and lignin, but can also include such other undigestible components as oyster shells and synthetic polymers. Usual sources of dietary fibre added to animal diets include: straw, hay (particularly from mature grass), ensiled forages, grain husks, legume seed coats, sugarbeet pulp and some by-products. Different sources of fibre will contribute to effective digestion to varying extents and will usually have both chemical and physical properties that are important for adequate digestion. However, some sources - for example, highly comminuted fibre - will have only the chemical properties.

A diet high in fibre is the normal diet of the grazing ruminant. Intensive production systems that incorporate energy-rich concentrates at the expense of dietary fibre risk physical damage to the ruminal epithelium, but are fed because they can satisfy the energy requirements of animals that have been bred for high levels of production. In acidosis caused by inadequate fibre intake, there is accelerated fermentation in the rumen leading to reduced ruminal pH. This disrupts the normal range of microbial flora in the rumen (and therefore the products of fermentation - increasing propionic and butyric acid production while reducing that of acetic acid) but also damages the ruminal wall itself, causing lesions, abscesses and malformation of the ruminal papillae. This acidotic state is presumed to be uncomfortable for the animal, and certainly leads to reduced intakes and the multitude of welfare and production impacts arising from a poor state of nutrition. Ruminal acidosis has also been associated with laminitis and displaced abomasum.

The behavioural act of **rumination** is the process of repeated chewing and addition of saliva in order to increase the surface area of dietary fibre particles and release soluble nutrients from the severed ends of fibre particles. Rumination bouts can last up to 30 min. It is a normal behaviour, and should be encouraged, in addition to which it is performed when the animal is at ease (see: **Comfort behaviour**), so is a good indicator of **welfare**. Feed that is low in dietary fibre will not be regurgitated, and in this case the animal will spend much less of its time ruminating, which can result in behavioural disorders. Dietary fibre, spending longer in the rumen than more rapidly fermentable dietary components, ensures that the rumen remains active for longer. This is an advantage to ruminants in colder environments, as the fermenting rumen is a considerable source of heat to the animal.

Dietary fibre is also important for the monogastric animal, feeding the natural microbial population of the hindgut, increasing the transit time of digesta through the gut and increasing the bulk of faeces. The hindgut microflora are able to digest the fibre and supply volatile fatty acids as an energy source, thereby lowering the pH and discouraging the proliferation of other harmful microorganisms (particularly coliforms) that can cause inflammation of the gut wall. The increase in transit time should result in greater digestive efficiency, as the digesta spend a longer period of time in each sector of the gut. Reduced time spent chewing on low-fibre diets can impair dental and jaw health in the rabbit. Additionally, the provision of dietary fibre (straw) in the bedding of the pig provides the animal with the opportunity to perform rooting behaviour. Pigs choose to spend about 20% of their time rooting in straw when given the opportunity to do so, and will preferentially select straw bedding over concrete housing.

Fractions in the diet that require more complex ingestion and digestion engage the animal in natural activities that can offset **boredom** and the expression of **stereotypies** deriving from inactivity. Improvements in the welfare of captive animals by the addition of dietary fibre into the diet, through

P.176

encouraging the expression of normal behaviours and decreasing the incidence of **abnormal** behaviours, have been observed in production systems (cattle, pigs, laying hens), in zoos (giraffe, elephant and possibly gorilla) and in other captive animals (horse and rabbit).

The horse is a grazing animal that can spend 12 or more hours a day feeding at pasture. If their diet is low in dietary fibre the feeding time is much reduced, as the easily ingested and digested concentrates pass quickly through the GI system. This can lead to behavioural problems such as **pica** and stereotypic behaviours and health problems, principally colic.

Similarly, an animal without a great deal to occupy its time, and that in the wild would have spent that time seeking food (estimated to be 75% of the time in the elephant), may feel a strong **motivation** to feed. The provision of dietary fibre, which might satisfy such a need without concomitant overnutrition, has been recommended for pigs. Perhaps related to this satisfaction of the motivational drive to feed, and therefore not leaving an animal in a state of **frustration**, increasing dietary fibre for pigs has been shown to reduce incidents of **tail biting** and other expressions of **aggression** and for rabbits has reduced the incidence of fur chewing, bar biting and aggression.

The addition of dietary fibre to the diets of dogs, cats and rabbits has been used to assist in the treatment of diabetes, colitis, constipation and obesity. Dietary fibre in poultry also speeds the passage of digesta and, as with the monogastric mammal, improves the environment for beneficial gut microbes at the expense of harmful bacteria. Intakes are increased, and this may reduce **cannibalism** in laying hens by increasing the time spent feeding. Herbivorous reptiles, of which there are few, such as the iguana and the tortoise, digest fibre in much the same way as monogastric herbivorous mammals. Digestive problems have been reported for the tortoise fed insufficient dietary fibre.

Perceived problems of adding fibre to animal diets include the generation of greater amounts of faeces, the welfare problems arising from larger amounts of slurry in bedding and the difficulties of their removal. Against this, however, amounts of nitrogenous material in the animal waste are reduced, in both pigs and poultry. Ammonia emissions and other odorous compounds have thus been found to be reduced in the manure and, subsequently, bedding of laying hens, broilers and pigs, thereby improving the environmental conditions for these animals and positively affecting their **health**, welfare and levels of production.

(DA)

Discrimination

Discrimination (cf. **generalization**) arises when examining whether an animal's behaviour is controlled specifically by one stimulus rather than another. As an example, consider the case in which an animal has learned to produce a particular action in the presence of a specific cue. While generalization refers to the animal's tendency to perform the action in response to other cues, discrimination is the extent to which the animal does not perform that action in response to other cues. A *generalization gradient* is the rate at which the tendency to perform the action changes with test cues that are more distinct from the trained cue. For example, if the animal has been trained to respond to a 1000 Hz tone, it will also respond (though less vigorously) to a 500 Hz tone or a 2000 Hz tone, and may also respond, though even less vigorously, to a 100 Hz tone or 10,000 Hz tone. Importantly, the generalization gradient can be altered by explicit discrimination training.

Any form of training necessarily consists of trials in which the target cue (e.g. the 1000 Hz tone) is presented and the animal is rewarded for producing the specific action. During explicit discrimination training, these trials are intermixed with trials in which other cues (such as 500 and 2000 Hz tones) are presented and the animal is not rewarded if it performs the action. Not surprisingly, the animal learns to suppress responses to these non-rewarded cues, and thus successfully discriminates between them. Interestingly, while explicit training of this sort is the most effective way to establish discrimination, an improvement in the ability to discriminate between cues (i.e. a decrease in the tendency to generalize) can be achieved simply by exposing the animal to these different cues prior to training (Mackintosh and Bennett, 1998).

Disease

Clinical disease may have profound influences on animal behaviour. In the later stages of infection in many serious diseases (for instance, BSE in cows), the behaviour of animals is affected to such an extent that it is obvious even to the untrained eye. This may include changes in the posture, **vocalization** and sequences of behaviour. A sick animal might be reluctant to stand, eat or drink and may show general signs of malaise. Some of these behavioural changes may also provide direct clues as to which body part or system is affected. For example, an animal kicking at its belly probably has an abdominal pain that is caused by colitis or other digestive system disturbances. Cats and dogs often tilt their heads when they suffer from ear infections. Excessive scratching that leads to skin damage and bleeding may be indicative of the presence of skin parasites or other skin infections. **Lameness** results in characteristic changes in gait. Animals with fever adopt a crouching position and may show shivering. Many diseases lead to characteristic changes in behaviour, which are an important aid to selecting the most appropriate intervention by the animal keeper and veterinarian and are often described in veterinary handbooks.

Much more challenging is the detection of the, frequently, more subtle changes in behaviour associated with **subclinical** disease and with the early stages of diseases that have the potential to develop clinical signs. In both cases, early detection of problems has important benefits, both for the **health** and **welfare** of animals and for economic reasons. In order to recognize such behavioural changes, a sound understanding of the 'normal' animal behaviour routine is required. Knowledge of the social dynamics within a group of animals and changes in them may also reveal the presence of disease. Dominant animals

that usually feed first when fresh food is presented to them or enter the milking parlour first may start to hang back

P.177

during the course of subclinical illness. Experienced personnel that know individual animals can be excellent at detecting such changes. However, the decrease in contact between stockperson and stock in most production systems means that this is frequently no longer the case. Systems that automatically record and analyse (aspects of) animal behaviour will, therefore, increasingly be relied upon for the detection of such changes.

In most cases of subclinical disease the clearest behavioural modification seen is a change in the animal's **feeding and drinking behaviour**. Infectious challenges that lead to subclinical disease generally result in a reduction of the daily food intake of at least 10-20%. The occurrence, extent and duration of this so-called 'pathogen-induced anorexia' will depend on the type of challenge and the ability of the animal to eventually overcome it. In bacterial infections the reduction could occur within a number of hours post-challenge and last for only a few days. In infections with gastrointestinal parasites there is a substantial delay in the onset of 'anorexia', which may last for a number of weeks (see Fig. D.8).

Automatic recording of water and food intake at the group or individual level may thus facilitate early detection of disease problems. For some systems, automatic detection of behavioural changes caused by subclinical disease is most appropriately carried out at the group level. In the UK, for example, pig producers are encouraged to install water meters that measure daily water consumption per housing unit, and to use changes in water consumption as a problem identification aid. A slowing in the drinking rate from electronic milk feeders is advocated as an early indicator of health problems in systems for dairy and beef calves.

Other systems may be based on the capture of (feeding and drinking) behaviour of individuals, especially for larger animals such as cattle and sows that may be equipped with electronic tags. This allows a much more subtle approach to health challenges individual animals may face. For instance, locomotory problems (often accompanied by lameness) may not result in changes in daily food intake, but can be recognized from profound changes in short-term feeding behaviour such as eating rate. Such characteristic changes are likely to be due to hungry animals that attempt to reduce the time spent feeding because standing at the feeder is painful. Automatic analysis of animal feeding and drinking behaviour may be linked with other automated recording systems (such as data obtained in the milking parlour for dairy cows) to facilitate early detection of disease from subtle changes in behaviour.

The final category of changes in behaviour caused by health challenges includes modifications that are undetectable even by analysis in terms of number and duration of bouts of behaviour. Such changes appear during the early stages of health challenges and affect mainly the complexity of behaviour, as indicated by fractal analysis. For instance, a reduction in the complexity of the pattern of vigilance and feeding behaviours has been observed in grazing animals that are infected by parasites. Standard measurements of behaviour cannot reveal such changes, since in the above case both parasitized and non-parasitized animals spent the same amount of time feeding and performed the same number of head lifts. However, the temporal patterns of these behaviours, i.e. their complexity, were significantly affected by parasitism.

Good stockmanship is based on a profound knowledge of normal animal behavioural patterns, and the manner in which they are affected by health challenges can be an important aid in the early detection of disease. However, as interactions between livestock and farm personnel decrease, more sophisticated systems to detect changes in animal behaviour caused by subclinical disease will be required. Detection of subtle changes in behaviour is consuming in terms of both time and resources. In order for these changes to be used as a means of early detection of health and welfare problems, the following system needs to be in place: (i) one that automatically captures these behaviours; (ii) one that analyses the behaviours and compares them with 'normal' behaviours; and (iii) one that delivers warnings that arise from those modifications of behaviour, but also minimizes the number of false warnings. Automation in the capture of behaviours, such as feeding, is now becoming increasingly available, even in conventional systems of production. The challenge lies in incorporating these into an automated early health detection system.

Dishabituation

Dishabituation refers to the reinstatement of a reflex response to a stimulus to which the animal had previously become habituated (reduced responding as a result of learning about the non-significance of the event). Dishabituation arises as a result of 'forgetting' about the previous learning experience, rather than due to a new association between the stimulus and its consequences (this would be a new form of learning). It has

P.178

been proposed that dishabituation may arise in some circumstances as a result of non-specific stress in animals (stress-induced dishabituation), and so the reappearance of a response may be an indicator of non-specific **welfare** problems in the management of the animal.

(DSM)

See also: Habituation

Disinhibition

The term disinhibition is used in a variety of contexts within applied animal behaviour. Within the context of behavioural control, it is used to describe less restrained behaviour. Some drugs (notably **benzodiazepines**) are reported to result in the disinhibition of behaviour (disinhibition of **aggression** is of particular concern with these drugs), i.e. as a result of their tranquillization effect the animal is less restrained in its behaviour and so may be more willing to engage in an aggressive encounter, where previously it would not.

Within learning theory the term disinhibition is used particularly in relation to classical conditioning (**see: Conditioning - types of**) to refer to the spontaneous appearance of a previously extinguished response in association with a novel stimulus.

(DSM)

Disorders of behaviour

The term behavioural disorder is often used to describe a syndrome of one or more **abnormal** behaviours exhibited by an individual, and so the term is often used interchangeably with '**problem behaviour**'. However, strictly speaking, the term should refer only to conditions incorporating malfunctional responses, since the disordering of behaviour reduces its function. Disordering produces a variant of a normal behaviour pattern. Malfunctional behaviour will typically be **maladaptive**, but the reverse is not necessarily the case, i.e. a maladaptive behaviour is not necessarily malfunctional, because it is possible for normal adaptive behaviour patterns to be maladaptive if they are expressed in an inappropriate context, e.g. escape attempts when escape is not possible.

Dispersal and habitat selection

Animals that leave an original site, **home range** or **territory** and eventually settle in a new location are called dispersers. Natal dispersal occurs when an individual leaves the area in which it was born and settles in a new area where it will spend biologically significant amounts of time. Many animals make additional movements after natal dispersal, but typically the distances travelled during natal dispersal are longer than those traversed later in life. Hence, for many animals, natal dispersal is the period during which individuals are most likely to move long distances through unfamiliar terrain before settling in a new location.

Within a given species, there is often considerable variation in dispersal tendencies or distances. For instance, in some squirrels, most females settle close to their natal home range, but a few females leave their natal neighborhood and make long-distance movements before settling in a new home range. Sex differences in dispersal tendencies and distances are also commonly observed. In mammals, males usually disperse farther than females, whereas the reverse is typically true for birds. Because the behavioural processes affecting the behaviour of dispersers may vary as a function of dispersal distance (see below), it is sometimes convenient to categorize individuals in terms of their dispersal distances, e.g.: (i) 'non-dispersers' or 'philopatric' individuals, which remain in or very close to their natal site; (ii) 'local dispersers', which settle in new sites within the same neighbourhood; or (iii) 'long-distance dispersers', which travel long distances before settling in a new location.

Within a given population, some individuals are usually more likely to disperse than others. Typically, natal dispersal occurs at a particular age, life stage and/or season. In addition, individual differences in the tendency to disperse or in behaviour during dispersal may be related to the condition of individuals at the time/age or stage of dispersal, conditions in the habitat of origin at the time of dispersal or interactions between these factors.

While it is clear that dispersers often differ from non-dispersers within the same population, we currently lack a general framework to predict which individuals are most likely to become dispersers in any given species. Once in a while, there are clear morphological differences between dispersers and non-dispersers. Thus, insects such as aphids have both winged and wingless forms, and it is reasonably easy to predict that the former would be likely to disperse over longer distances than the latter. However, diagnostic morphological features that can be used to distinguish dispersers from non-dispersers are less often encountered in vertebrates. In naked mole rats (a highly specialized fossorial mammal), dispersers have higher body mass than non-dispersers of the same age in the same cohort, and larger body masses for dispersers have been reported for a scattering of other species. However, there are many other vertebrates in which there are no discernable differences in mass between dispersers and non-dispersers, or in which dispersers are lighter than non-dispersers.

Because dispersal is a behavioural process, behavioural factors are as likely to generate variation in dispersal behaviour as are inter-individual differences in physiology or morphology. A variety of behavioural differences between dispersers and non-dispersers has been reported in insects, and recent studies of great tits, an avian species, indicate that dispersers and non-dispersers differ with respect to a **personality** type (fast-slow), which is also related to a host of other behavioural traits (including aggressive and exploratory behaviour) in this species. These and similar studies suggest that it might eventually be practical to identify potential dispersers before they leave by scoring particular diagnostic behaviours or other traits.

One reason why applied biologists should be concerned about correctly identifying potential dispersers is that these are the individuals most likely to be willing to accept and settle in an unfamiliar habitat. Hence, if the goal is to move animals from a familiar to a novel location in captivity, to release captive-

raised animals into the field or to transfer free-living animals from one area to another, success is more likely if the

P.179

translocated animals are at the age, stage and condition in which they would naturally be most likely to move and settle in a novel habitat.

From the perspective of the animals that are doing the dispersing, it is important to remember that the goal is not simply to travel away from the point of origin, but also (and more importantly) to locate a new high-quality area in which to live. Hence, dispersal is intimately related to habitat selection, where habitat selection is the behavioural process that governs a disperser's decision about when and where to settle after leaving its habitat of origin.

Traditionally, most theoretical and empirical studies of habitat selection have been based on the assumption that animals can freely choose between different types of habitats, and choose the habitat in which they are likely to have the highest fitness after settlement. This assumption is embedded within the most influential general model of habitat selection (the **ideal free distribution**), which assumes that every disperser is free to settle in the habitat in which it will enjoy the highest fitness. Since the ideal free distribution model was introduced in the 1970s, theoreticians have devised many variants of the original model, including models which consider the effects of assessment errors, conspecific or heterospecific competitors, or cooperative conspecifics on the choices animals make when selecting new habitats.

However, until recently, most habitat selection theory has focused on situations in which habitat selection is low cost or cost-free, in the sense that animals are assumed to have an unlimited amount of time (or energy) available to them to visit, assess and select habitats that are available to them. In the context of habitat selection by dispersers, this assumption may be reasonable when individuals disperse over relatively short distances, when travel costs are low and when animals are able to sample many different new habitats prior to choosing a new one. However, this assumption is less likely to be true for long-distance dispersers that have a limited amount of time or energy available in which to search for a new habitat.

Recently, field workers and modellers have become interested in factors that might affect habitat selection for time- or energy-limited dispersers, particularly those that encounter relatively few suitable habitats after leaving their habitat of origin. In this situation, theory suggests that habitat selection is unlikely to be an 'all or nothing' phenomenon, and that individuals should often be more selective (more choosy) at the beginning of the search period than at the end of it. Data supporting this prediction are available for the larval dispersers of many types of marine invertebrates, where declines in selectivity during search are explained by the 'desperate larva' hypothesis. This colourful phrase reflects the main reason why one would expect disperser selectivity to decline over the course of the search period: it may be better to be non-choosy (willing to settle in less preferred types of habitat) than to be dead (as a result of continuing to 'hold out' for a highly preferred type of habitat). Experimental data indicating that selectivity declines during search have also been obtained for insects searching for new habitats, hosts or oviposition sites. However, thus far we lack evidence that this phenomenon occurs in vertebrates.

Another traditional assumption of habitat selection theory is that all of the members of a given population prefer the same type of habitat. That is - with appropriate allowances for errors in habitat classification or assessment - most current studies assume that every individual in a population should rank alternative potential habitats in the same way. However, there is another body of literature that suggests that this may not always be the case. For instance, the concept of 'habitat **imprinting**' suggests that exposure to particular cues in a natal habitat may increase a disperser's preference for new habitats that contain those same cues.

Similarly, entomologists have found that early experience with a particular type of host, food or oviposition site may increase a disperser's preference for the same type of item, a phenomenon they have called 'preference induction'. With respect to habitat selection by dispersers, these and related terms fall under the 'umbrella concept' of natal habitat preference induction (NHPI), which includes a variety of processes by which experience in a natal habitat increases a disperser's level of preference for new habitats that contain cues comparable to the cues in its natal habitat. Thus far, NHPI has been documented in a wide range of taxa, including social and non-social insects and a scattering of vertebrates.

The concept of NHPI has a number of interesting implications for problems in applied biology. Indeed, many of the best empirical studies of NHPI to date have been conducted by entomologists whose goal was to use parasitoid wasps as biological control agents. These scientists have identified a number of ways in which early experience with a given host and with habitat features associated with that host can affect the habitat preferences of newly emerged parasitoids. One impetus for this line of research was a series of failed attempts at biological control, when it was found that parasitoids raised in captivity on convenient artificial hosts and habitats were ineffective at controlling their target host after being released into natural landscapes.

In addition, NHPI has interesting and potentially important implications for problems in conservation biology, particularly those involving the transfer of animals born and raised in one habitat to a new, unfamiliar habitat. Success rates for captive release and translocation studies are often low because the newly released animals refuse to settle at the new location, and instead emigrate away from the release site into surrounding areas. Problems inducing animals to settle in unfamiliar habitats occur even when other evidence indicates that these habitats are highly suitable for the members of that species. An NHPI approach argues that a mismatch between the experience and cues in the habitat of origin and conditions and cues in the new habitat may contribute to an individual's reluctance to settle in habitats that are perfectly suitable for the members of their species. Hence, a perspective on habitat selection that assumes that habitat preferences are not fixed, but are instead affected by an individual's experience in its previous habitat, may be helpful for increasing the success rates for management programmes that have the goal of inducing animals to settle in habitats that are new to them.

Displacement behaviour

A displacement behaviour usually arises when there is motivational conflict or **frustration**, and is a normal behaviour that is performed in a different, and apparently inappropriate, situation from the one in which it is usually performed. A typical displacement behaviour in cats is a grooming lick between the shoulder blades, and it might occur if a cat suddenly appears in an unexpectedly aversive environment (e.g. comes downstairs and sees there is a dog in the house). It is often a simple behaviour that is of no relevance to the current situation.

Display behaviour

Display behaviour is a specially evolved pattern of behaviour that functions to convey information between individuals. The 'specially evolved' caveat relates to those aspects of an animal's behaviour that are highly exaggerated, conspicuous and ritualized (**see also: Ritualization**), which allow the distinction between display and **communication** to be made. Displays are usually associated with either mating rituals (**see: Mating behaviour and systems**) or contests over resources (**see: Agonistic behaviour**), and generally function to aid information transfer between individuals, with the vigour or magnitude of the display supposedly providing honest and reliable information about the signaller.

For example, during animal contests, displays tend to enable competitors to resolve conflicts without resorting to costly physical combat, because the display provides reliable information about the fighting ability of the contestants. However, displays do not always convey reliable information as they may manipulate the receiver into behaving in a particular way that is beneficial to the sender and costly to the receiver. For example, during contests over cavities in rocks and coral, mantis shrimps (Stomatopoda) use the 'meral spread' threat display (the spreading of the raptorial and walking appendages) as an indicator of motivation and aggressiveness during an encounter. This is usually a reliable indicator of fighting ability, although it is known that some newly moulted individuals produce this display despite the fact that they have soft exoskeletons and would thus be poor competitors during a contest. With manipulation comes counter-selection on the part of the receiver not to be manipulated by the deception (**see: Deceit behaviour**). Thus, receivers should (in theory) not respond to displays (or elements of the display) that convey dishonest information. In effect, receivers select for honest signallers, although the selective pressure to manipulate or deceive others will ensure that displays are not 100% honest 100% of the time.

Distress

Derived from the Greek word *dus* and having a connotation of poor function, or malfunction. Applied to stress it infers that an animal is not coping with its situation in some way, leading to a stress response involving stimulation of a sequence of glands, i.e. the **hypothalamus** releases hormones that stimulate the **pituitary gland** to release hormones that stimulate the cortex of the **adrenal gland** to release **corticosteroids** that affect various body systems in various ways. For distress to occur, it has to persist to a point where it becomes pathological in some way, i.e. outside the normal range of an adaptive stress response. Some use the term distress to describe any situation where there are raised blood corticosteroid levels. However, this is too blunt an approach, as corticosteroids can also rise during exercise and during pleasurable events. Furthermore, distress can be used to describe short-term experiences, such as transient pain, as well as the long-term effects of not coping, such as fear, frustration and so on.

(DBM)

Diurnal pattern or rhythm

A diurnal pattern is a biological pattern occurring with a pattern of about 24 h. It should not to be used synonymously with **circadian rhythm**, even though they both have approximate 24 h rhythmicity. Strictly speaking, a true circadian pattern is endogenously generated - i.e. exists without external cues. Diurnal rhythms are generated in response to external cues such as the day-night cycle. Both free-living animals and domestic animals housed in a variety of systems show strong diurnal patterns in behavioural activity. For free-living animals, the major factor influencing behaviour is the need to acquire nutrition. The amount of time spent each day engaged in feeding-related activities will vary depending on whether the animal is a herbivore, omnivore or carnivore but, in all cases, will still show diurnal variation.

Herbivores may show variation in activity related to when it is coolest, warmest or safest to forage. Many free-living ungulates show peaks in activity around sunrise and towards sunset, when there are thermoregulatory benefits. Not surprisingly, carnivores will match their activity patterns to their prey species - for example, African wild dogs make most of their kills in the 2 h after sunrise and in the 1 h after sunset. As with foraging, other behaviours will also show diurnal patterns and synchronicity within the herd/group. For example, free-ranging pigs may intersperse periods of foraging-related activity with resting, social interaction, wallowing, etc.

Within the applied animal behaviour and welfare field, diurnal patterns have been most studied with regard to behaviour. As well as general activity, specific behaviours studied include **stereotypies**, **feeding**, **dust bathing**,

P.181

drinking, standing, walking and feather pecking. With pigs, it has been shown that **bar biting** of confined gestating sows shows a diurnal pattern, related to feeding time, with a peak in occurrence over the 2 h immediately following **feeding**. Pigs show diurnal patterns in lying behaviour and in posture, showing an increase in lateral lying and lying in contact with pen-mates during the night, and these amounts can be influenced by fluctuations in the external temperature. Drinking by newly weaned piglets shows a diurnal pattern, with maximum intake around late afternoon and minimum intake before dawn. It has been speculated that this pattern is so stable in healthy pigs that changes in pattern could be used automatically to detect disease.

Poultry have diurnal patterns in feeding behaviour and, unsurprisingly, **perching** behaviour that can be influenced by day length. Free-range broilers show maximal outdoor use at sunrise and sunset, and those birds subject to natural light as opposed to artificial light show earlier perching, presumably as light gradually begins to fade. For broiler-breeders that are fed restricted diets, diurnal patterns exist in resting, preening, standing, walking and stereotyped pecking. Poultry also show diurnal patterns in dust bathing and **feather pecking**.

For grazing ruminants such as dairy cattle and captive red deer, there are again diurnal patterns of activity, but superimposed upon these are **ultradian rhythms**, most probably associated with rumination. Horses also show ultradian patterns in grazing superimposed upon diurnal patterns. Again, for grazers, patterns can be influenced by management, and diurnal patterns of dairy cows have been shown to differ between a continuous stocking system and a strip-grazing system.

Diurnal patterns have also been investigated physiologically, but there is the difficulty in discerning whether patterns are circadian (i.e. endogenous) or truly diurnal, and also the confusing use of the terms diurnal and circadian as if they were interchangeable. For example, researchers have investigated heart rate over the course of 24 h and found it to be higher during daytime than during night-time. However, activity levels are also higher during daytime and, although it has been reported that a circadian pattern exists for heart rate, without evidence of rhythmicity in the absence of light cycle and activity patterns, the pattern should be described as diurnal rather than circadian.

In general, investigations of diurnal patterns have not been fully exploited in animal **welfare** research, and many more opportunities exist for their use as a welfare assessment tool.

DNA analysis

Deoxyribonucleic acid (DNA), the 'building blocks of life', consists of a double helix of two strands of alternating sugar (deoxyribose) and phosphate groups linked to nitrogenous bases (the four bases are adenine, cytosine, guanine and thymine: thymine always pairs with adenine, and cytosine with guanine). These bases are arranged in specific sequences that code for the production of proteins. The study of genes and their sequences is known as genomics, and the translation of the genes into proteins as proteomics.

There are thought to be around 30,000 genes in the mammalian nucleus, many of them shared between the various species. DNA analysis aims to sort out the sequences within the genome and to identify the

sequence of each gene - as well as the flanking sequences of non-gene-coding DNA - and their functions. Some of these flanking sequences repeat at intervals (micro- and mini-satellites) that enable individuals to be identified, forming the basis of DNA fingerprinting. It is so discriminating that it is believed that every human being on this planet can be identified, apart from identical twins. The genetic basis for behaviour is a growing subject of research at the molecular level.

(DBM)

Docking - tail

Tail docking is performed on a variety of species: **pigs**, **sheep**, **horses**, **dogs** and, most recently, **cattle**. The reasons for tail docking are to prevent injury to the tail, to prevent spread of **disease**, to improve appearance or to facilitate harnessing. The welfare issues concerning tail docking fall into two categories: (i) the **pain** caused by the initial removal; and (ii) the consequences of loss of the tail to the animal's long-term **welfare**, behaviour and comfort.

Pain

The method of tail docking differs from species to species and country to country. In general, puppy, piglet and horse tails are cut off, but lambs and cattle may be docked using either knives or bands. When the two methods are compared, the initial pain is greater with cutting, but the ischaemic pain of the bands lasts longer. The signs of pain following docking also vary with the method. Puppies shrieked a mean of 25 times when their tails were amputated (Noonan *et al.*, 1996). Cattle abduct their tails. Lambs show abnormal postures for days after banding (Wood and Molony, 1992). Piglets vocalize at the time of docking, but less so when in response to an injection of penicillin. There are many other behavioural responses as well, but these remain to be quantified.

Consequences of docking

The function of the tail elucidates the welfare problems that might arise from its loss. Tails are used in **communication** in almost all species and for insect control in ungulates. Finally, in carnivores, and possibly in other classes of animals as well, the tail is used for balance. Tail position is an especially important signal in dogs. The stiff upright tail indicates arousal and **aggression**. The wagging tail indicates anticipation, usually pleasurable. The lashing tail in the horse, cow and cat is a sign of frustration. Raised tails function as a **play** signal in calves and can be a sign of oestrus in many species.

P.182

The depressed tail, held close to the body, indicates **fear** in almost all species. Both calves and lambs wag their tails while suckling (see: **Nursing**). In conventional pigs, the curl of the tail is an indicator of well-being in that a flaccid tail connotes fatigue or discomfort. In piglets, the tightly curled, tense tail indicates that the sow is letting down milk, i.e. the piglet is swallowing milk. Whether pigs use tail position and curliness as signals has not yet been ascertained. Some breeds, notably Vietnamese pot-bellied pigs, do not curl their tails.

The balance function of the canine tail is most apparent when the dog has developed hind limb lameness or pain. At that time, the dog will deflect the tail in an exaggerated manner, presumably to help keep its balance while minimizing weight bearing by the painful limb. No one has compared the number of falls suffered by docked dogs such as Rottweilers and Australian shepherds with those of undocked dogs of the same breed. These dogs may have learned to compensate for the loss of their tails.

Tail docking of draught horses, hackney ponies and other horses that wear cruppers (a belt attached to the saddle and looped around the tail head to prevent the saddle slipping forward) renders them vulnerable to insect bites. The long-haired tail of the horse functions as a more efficient fly swatter than

the tufted tail of cattle. The number of flies settling on docked horses or the frequency of self-grooming and rubbing movements have not been quantified. Because the tail functions in communication, one would expect aggression to escalate more often because the conspecific was not aware of the threats implied by a lashing tail. The docked horse would have to lift its hind limb or actually kick rather than simply lash its tail.

The history of tail docking of cattle is recent and, for that reason, this **mutilation** may be the easiest to legislate against. Originally, tail docking was performed to reduce the spread of leptospirosis from cow to person or cow to cow in New Zealand. The practice spread to the USA, where it was alleged to reduce the risk of **mastitis** because the cows would not become so dirty. In fact, in the free-stall situation, docked cows have neither a cleaner coat nor a lower incidence of mastitis than intact cows (Stull *et al.*, 2002).

The real reason for the popularity of bovine tail docking is that it prevents the milker from being hit in the face with a manure-laden tail. One alternative is simply to clamp the tail out of the way during milking; another is a system in which the cow is above the milker so that the human's face is out of tail range. Finally, **robotic milking** could solve the problem entirely.

Pigs are tail docked at birth or within a few days of birth. The reason for docking porcine tails is the problem of **tail biting**, a sporadic behaviour that injures the victim's tail and can cause ascending infections that will lead to condemnation of the most valuable part of the carcass, the hams. For that reason, some **slaughterhouses** will not accept pigs with intact tails. Farms that do not have tail-biting problems are, therefore, forced to dock tails. Tail biting apparently arises when pigs are foraging and encounter a tail that is similar in size and shape to the worms and snakes they might eat in a free-ranging situation. Once the tail is bitten and the pig tastes blood, it may bite more frequently because it apparently prefers iron-rich substrates such as blood. Iron-rich supplementation might help reduce levels of tail biting. Bedding in which the pigs can forage would probably also reduce the problem.

Dog

The canid or dog family consists of true foxes (vulpini, which consist of species of the genera *Vulpes* and *Urocyon*), basal canids (or basal dogs, which include the raccoon dog and banded fox) and the more diverse true dogs (canini). The latter include the genus *Canis*, which consists of coyotes, the Ethiopian wolf and various genetic lines of the grey wolf (*Canis lupus*), including dingos, domestic dogs, Arabian

wolf, Indian wolf, red wolf and the New Guinea singing dog, some of which are considered distinct species in some texts. Also included among the true dogs are a range of other genera whose members often include the terms 'dog', 'fox' or 'wolf' in their title, such as the African wild/hunting dog (genus *Lycaon*), the Asian wild dog (genus *Cuon*, also known as the Dhole - it is worth noting that several other genera also include the name Dhole), bush dog (genus *Speothos*), crab-eating and Falkland Island fox (genus *Cerdocyon* and *Dusicyon*, respectively) and maned wolf (genus *Chrysocyon*).

Domestic dogs are believed to have diverged from the ancestral wolf in excess of 15,000 years ago, possibly up to 50,000 years ago, although some estimates place an upper limit potentially in excess of 100,000 years ago. Since this time the two have evolved in their own niches and so comparisons between the domestic dog and modern grey wolf (especially the North American timber wolf, which is so often pictured as the 'proto-dog' in popular texts) are of limited value, and the latter is not representative of the progenitor of the former; rather, they are perhaps best considered more like 'cousins'. It is generally accepted that the success of dogs is inextricably linked to the success of humans and the close relationship that has existed between them; indeed, the two may have co-evolved and have certain adaptations to aid their intraspecific communication (see below). One feature of the ancestral wolf that may have given rise to this potential is its natural range around the glacial edges, which would have favoured the conservation of genetic diversity given the relatively unstable environment.

Wolf-dog analogies are common, but there are several important limitations that need to be considered when such comparisons are made. First, as already mentioned, most comparisons appear to be with certain subspecies of North American grey wolf (of which there may be around 20) rather than with some of the potentially more relevant Asiatic subspecies. There are around a dozen subspecies of Asiatic

P.183

lupine wolf, and genetic studies suggest that only certain lines within some of these may have contributed significantly to the domestic dog population, emphasizing the danger of generalizations concerning the relationship between dog and wolf.

A second problem concerning such analogies focuses on comparative behavioural studies. Much of the information gleaned on wolf behaviour is derived from studies of captive wolf populations. In this context competition for resources and **social stress** may be greater, as **space** is more limited and feeding more controlled externally by managers. As a result there may be an overemphasis on behaviours related to **resource-holding potential** and competition, especially **aggression** and **agonistic behaviour**, and the importance of **hierarchy**, at the expense of recognition of the role of **affiliation**, **cooperation** and **bonding** in its **social behaviour**. Some have even suggested that, since wolves are not adapted to captivity through **domestication**, using the behaviour of wolves in captivity to understand dogs is like using the behaviour of dysfunctional people and those with mental health problems to understand the normal behaviour of humans.

A third potential problem with wolf-dog analogies relates to the changes that have occurred in the dog as a result of domestication. It seems that this may have resulted in both physical and behavioural pedomorphosis compared with the wild type, the young being more playful and cognitively flexible. In which case, analogies should be between the behaviour of immature rather than adult wolves (in whom hierarchy is much less rigidly defined) and adult dogs.

On top of this are the changes associated with selection for diverse functions in specific **breeds** of dogs, which are also likely to affect their behavioural style. The diversity in form and behaviour of dog breeds may reflect both the diversity of the ancestral population as well as pleiotropic effects associated with the processes of domestication and the selection for tameness (which appears to result in additional phenotypic changes), as well as specific selection for certain traits during the process of breed diversification.

In addition to obvious differences in physical form, it appears that the structure and functionality of the eye may also vary with conformation (McGreevy *et al.*, 2004), with long-nosed breeds (dolichocephalic) possessing a high acuity area within a visual streak, and short-nosed breeds (brachycephalic) more a focal spot (similar to primates). The former may be better suited to scanning the horizon and the latter for focusing on closer objects - and especially faces. This may explain in part why the ancient lapdogs tend to be shorter nosed and the sight hounds long nosed.

Although breeds of dogs are classified by Kennel Clubs into various functional groups (working, terrier, pastoral, etc.), this is not a phylogenetic classification, and distantly related breeds may appear in the same group. Genetic analysis suggests four broad groups (Parker *et al.*, 2004): (i) an ancient, largely Asiatic, group, containing the Shibu Inu, chow-chow and Akita, but also the basenji and malamute; (ii) a mastiff group, including boxers, Rottweilers and bulldog types; (iii) a herding group, consisting of many sheepdogs and the borzoi; and (iv) a more recent working and hunting group, including many terriers, spaniels, setters, etc., as well as the Border collie.

Originally, breed was linked to function but, with the advent of breed societies and showing, the form of the animal is now more often linked to a more arbitrary breed standard, often with an emphasis on physical appearance rather than function. This, together with the closure of breed stud books, has resulted in very restricted gene pools and, combined with a very high level of **inbreeding**, has resulted in a very high prevalence of genetic diseases in dogs. While some of these may be used as models of human conditions, their widespread distribution in the general population is a serious cause for concern.

Dogs appear to show an inherent sensitivity to human stimulus enhancement, although this may vary between breeds. Hand-reared and pet dogs also show greater attachment and attention to humans compared with hand-reared wolves, and this may explain in part some of the difference in learning performance between the two species, with the latter being more independent and less likely to seek assistance from a human handler during problem-solving tasks. The tendency to human attachment may also partly explain some of the problems seen in pet dogs, such as **separation anxiety**. Other adaptations that may have historically aided the development of the human-dog relationship include the playfulness of dogs and their social cognitive ability, especially in tasks relating to interspecific **communication**. This includes their capacity for specialist processing of information within human faces (Guo *et al.*, 2008) and the use of barking, which, intuitively, humans seem to be able to relate consistently to specific contexts (Pongracz *et al.*, 2005).

It has been hypothesized that dogs became domesticated as a result of scavenging from waste sites following the development of human settlements, with the advantage of obtaining substantial protein sources - possibly cooked and more readily digestible - with relatively little effort, providing strong selective pressure against **neophobia** and towards attraction to humans. Thus dogs may be considered omnivorous scavengers rather than obligate carnivores. Although dogs seem to be highly gregarious in the feral state, they do not necessarily form packs, especially when food resources - such as those that can be provided in association with people - are abundant.

Dogs exist within society in diverse contexts, ranging from the wild and feral through the free-ranging and cared for but unowned, to the owned and potentially highly restricted pet, working and sport animal, **laboratory animal** or **farmed animal**. The **welfare** issues obviously vary with context (see Stafford, 2007, for further details). Free-roaming dogs may directly and indirectly impinge on the welfare of others, as they are a major cause of road traffic accidents, zoonotic infections and damage to livestock, although they may also be preyed upon by large carnivores, including other canids.

Because bitches typically cycle twice a year, overpopulation can rapidly become a significant problem and, because dogs are a common vector for human infection by rabies, many regions take measures to control **feral** animals. **Abandoned animals** are also a significant problem, with more than 1% of the global population euthanased each year as a result. Neutering is encouraged to reduce unwanted and stray

animals, but its effectiveness is often limited in practice. Neutering does, however, also have beneficial effects for the individual (reduced risk of mammary tumours and elimination

P.184

of risk of infections of the womb in the female, reduced risk of prostatic diseases in the male, reduced roaming and other male typical behaviour), but may also increase reactivity and the risk of developing certain fears.

Problem behaviour is the most common reason for the relinquishment of dogs to **animal shelters** and is also a major reason for the **euthanasia** of pets. Problem elimination and lack of training appear to be particular behavioural risk factors for relinquishment, along with other non-behavioural factors such as not being neutered, being young, of mixed breed, obtained at little cost and unrealistic owner expectation. Aggression is a common reason for relinquishment, but is also quite prevalent in non-relinquished dogs and the most common reason for owners to seek professional behavioural advice. Other common reasons include separation problems and specific fears, which are also a cause for welfare concern.

Training is integral to the utility of the dog kept in most forms of captivity, whether it be a pet or used in work or sport. The methods used are increasingly attracting attention from both a welfare and ethical perspective (**see: Ethics**). There is growing advocacy for reward-based methods, but it is important to recognize that no training can be purely reward-based, since the absence of reward is a form of negative punishment (**see: Reinforcement - types of**), and failure to acknowledge this may result in the development of inappropriate or less effective training schedules and psychological distress. The use of strict schedules of positive reinforcement may also reduce the dog's ability to both problem solve independently and cope in psychologically stressful situations, and therefore potentially increase the risk of emotional problems. The training of dogs is therefore a complex but important welfare issue deserving further attention.

The dog was the first species to become domesticated and is one of the most ubiquitous species on the planet. It exhibits great variability, in both form and function, which arises as a result of latent potential both phylogenetically and ontogenetically. Their success has been supported by their close association with humans, and has resulted in them showing some remarkably human-like abilities. However, a rise in interest and acceptability of the dog as a topic for behavioural research suggests that this may often be the result of their great perceptual abilities and accommodation of people, and not due to similar processes at a mechanistic level. As a result the continued study of the dog may offer new insights into a range of important biological processes.

Domestication

Domestication is the process of enfolding a species into human society. It is distinct from both taming and the husbandry of wild animals in **captivity**. Only a very few animal species have proved capable of being domesticated, though any mammal or bird, if taken into husbandry at a very young age, will imprint on its human carers, becoming tamed as a result and accepting the carer as a socially dominant parent. However, on reaching adulthood, non-domesticated species exhibit their natural adult behaviours and can prove unmanageable. In contrast, domesticated species continue to accept the social **dominance** of humans into adulthood. The species that have proved amenable to domestication all have natural patterns of social behaviour that can be moulded in this way as part of the domestication process, typically, including dominance hierarchy and lack of territoriality.

In several species, notably the **dog**, many adult behaviours are in fact juvenile behaviours retained past the age when, in the natural state (i.e. in the progenitor species, the grey wolf) they would be superseded.

Presumably domestication, which for animals was first achieved about 10,000 years ago (though perhaps much earlier for the dog), involves genetic changes, though what these were remains unknown. Taming of young animals taken from the wild would have been the first step, and individuals that exhibited a greater response to the taming process would have been selected. Likewise, a tendency to retention of juvenile behaviours would be favoured.

Species differ in the completeness of the enfolding process. Fish and invertebrates probably do not have cognitive abilities of the kind that permit this enfolding. Considering mammals, Clutton-Brock (1987) visualized a spectrum, from 'man-made animals' (dog, **sheep**, **goat**, **pig**, **cattle**, equines) to 'exploited captives' (**cat**, **elephant**, **camelids**, reindeer, water **buffalo**, yak, Bali cattle and mithan). Small mammals (**rabbit**, ferret, **rodents** and fur-bearing carnivores) have been bred in captivity for much shorter periods of time, so should be regarded as being in the early stages of domestication. A similar spectrum can be envisaged for birds, with the **chicken**, duck and **turkey** as the most completely domesticated, and guinea fowl and **ostriches** less so.

P.185

Dominance

The term dominance can be used in both a genetic context and a **social behaviour** context. This article focuses on its use within animal behaviour. Animals that live or come together in groups develop various kinds of relationships with one another (**see also: Grouping**). One form of relationship is of a dominant-subordinate nature, where the dominant animal(s) has a higher status, recognized by influence or control over another or others in the group. Dominance is not an attribute or trait of an individual animal, but is an aspect of a dynamic relationship between two or more individuals, which may be of the same or different species.

For dominance to exist there must be a disparity or difference between the individuals, and this disparity can occur in any one (or more) of the factors or attributes that affect the outcome of an interaction. The disparity must also be detected by the participants and the appropriate responses made. The relationships between individuals can be: (i) learned, based on individual recognition and/or recognition of the disparities and their consequences; (ii) already established, based on cues that are correlated with disparities; or (iii) both mechanisms can operate.

Dominance will usually be most evident in situations in which two or more animals are crowded together or come into close proximity; the dominant individual apparently moves wherever it wishes while the subordinate(s) gives ground and moves away. Thus, the behaviour of the subordinate animal(s) is changed and/or inhibited by the presence of the more dominant animal. Indeed, this principle provides the basis of numerous techniques that have been developed for assessing or measuring dominance. Methods include displacement from a particular resource, such as food or water, or just displacement in space. Agonistic interactions (involving offensive and defensive behaviours such as threats, attacks, submissions and flight; **see also: Agonistic behaviour**) are also recorded because these can reveal 'winners' and 'losers', or whether interactions and relationships are unresolved.

There are many factors that influence the dominance potential of an individual and, thus, the outcome of an interaction. A major influence is reported to be the 'aggressiveness' of the individual, which can be considered to be an animal's propensity for displaying offensive or attack behaviours that have the potential to cause physical injury to another individual (**see also: Aggression**). Aggressiveness is influenced by several factors that are, also, likely to interact and influence each other. Factors affecting aggressiveness include:

1. Hormone levels (particularly the **androgens**). As a result of hormonal influences and concomitant morphology, such as large body size, broad shoulders and large horns or antlers, it is often the case that males are dominant to females. Hormonal changes, such as occur seasonally and according to reproductive status, will influence aggressiveness and dominance, for example during the breeding season and after the birth of offspring (**see also: Maternal behaviour**). Furthermore, hormones affect the expression of secondary sexual characteristics (e.g. antlers), and these characteristics are often non-arbitrary signals or cues of an animal's dominance potential, e.g. antler size is positively correlated with

dominance status. In ruminants, the presence of horns affects dominance, with animals possessing horns generally being dominant over those that do not.

2. Genetic predisposition, which means that individuals inherit an aggressive character, or that certain breeds and genotypes tend to be more aggressive/dominant over others. For example, it has been reported that Hereford bulls are generally dominant to Brahman bulls. Further, it has been suggested that physical fighting skills, such as agility and speed, are likely to be partially inherited.

3. Social and other experiences. Experience can take two forms: (i) being involved in an interaction and emerging the winner or loser; and/or (ii) learning social skills from others in the group. Research has shown that, in comparison with socially experienced heifers, naive ones in their first encounter spent longer fighting, were less submissive and took longer to establish their first social relationship, which was less stable. These findings indicate that some social skills, at least, have to be learned. Animals that have a history of winning encounters are more likely to be dominant than those with a history of losing. Previous winners tend to increase their readiness to attack, while consistent losers appear to generalize to all encounters and perform submissive behaviours that result in termination of the interaction. As a consequence they are likely to retain a low rank or status. Additionally, dominance potential can be influenced by the dominance status of the individual's parents. This may be a consequence of group members avoiding the young animal when it is close to its mother or father, and then this avoidance being carried over into situations when the young animal is alone. The young animal may also learn aggressive and social skills from its parents. It is probable that all of these factors are involved.

4. Other factors that affect dominance potential in many species, including sheep and goats, are body size and body weight, with larger and/or heavier animals being dominant to smaller/lighter ones. These factors appear less important in cattle, where dominance is correlated best with age and/or length of time spent in the herd. In most species, older individuals are dominant to younger ones until such time that age or injury impairs the physical ability of older animals to fight.

There is also a so-called 'home court advantage', which is said to influence dominance potential, with individuals that are on home ground (**see also: Home range**) or holding/defending a territory (**see also: Territoriality**) having an advantage over intruders during social interactions. It has been suggested that an unfamiliar environment heightens fear and increased defensiveness and, hence, an intruder's intrinsic level of aggression and offensive behaviours will be reduced in contrast to an animal in a familiar environment.

Being the dominant individual is said to have advantages, such as having access to the highest-quality resources or, if resources are restricted and defensible, access to the resources at the expense of other, less dominant, animals. If such a system operates, then it is probable that the **welfare** of the dominant animal will be enhanced. The corollary is that the welfare of subordinate animals could be poor. However, being dominant also has associated 'costs' for the individual in some situations, as dominance may require constant vigilance and defence of

P.186

resources, which may reduce the animal's welfare and **fitness**. It is probable that there are degrees of subordination, with some individuals that will frequently challenge others in order to elevate their status, while others will rarely or never do so. In some circumstances the welfare and fitness of these latter animals will be better than any other animal in the group, but rarely would the welfare and fitness of the former be good.

Whether dominance influences access to resources appears to be species- and situation-specific; for example, in one study subordinate goats were found to be heavily parasitized as a consequence of having access to food prevented by dominant animals until the food had become spread out, trampled and contaminated. In contrast, in a study of beef cattle with severe restriction on feeding space, but more or less *ad libitum* availability of food, dominant animals did not prevent subordinates from accessing the

feeding stall. Dominant cattle have, however, been shown to select the 'best' resting sites, which could adversely affect subordinates if they were forced to rest in adverse microclimates, such as unsheltered sites or areas with poor air quality (e.g. high levels of noxious gases, high temperature, high humidity).

There are very evident adverse consequences for welfare, such as physical exhaustion and injuries, in situations where there is frequent aggression and fighting, as a result of disruptions to social relationships. For these reasons, mixing of unfamiliar animals should be kept to a minimum. Social tension may not always be manifested overtly, e.g. through physical interactions, but this does not mean that individuals are not experiencing **social stress**. Social stress, like other kinds of stress, if sufficiently severe, can have profound effects on welfare, such as increased susceptibility to **disease** and illness as a consequence of impaired immune function.

Dopamine

Dopamine (DA, 3,4-dihydroxyphenylethylamine) is the immediate metabolic precursor of **norepinephrine** and **epinephrine**. DA itself is a neurotransmitter activating dopamine receptors, and a neurohormone inhibiting **prolactin** release from the **pituitary gland**. DA cannot cross the blood-brain barrier. Within the **central nervous system** (CNS), DA is synthesized from the amino acid L-tyrosine, derived from dietary proteins and phenylalanine metabolism in the liver, which is taken up into dopaminergic **neuron(e)s** from plasma. Tyrosine is hydroxylated by the enzyme tyrosine hydroxylase (TH, rate-limiting enzyme) to 3,4-dihydroxyphenylalanine (L-DOPA). L-DOPA is decarboxylated by L-aromatic amino acid decarboxylase (DOPA decarboxylase) to form DA.

Following synthesis, DA is transported to axon terminals and stored in synaptic vesicles. It is released into the synaptic cleft in response to depolarization of the axon terminal (action potentials). There are several metabolic pathways of the released DA, e.g. coupled to dopaminergic receptors, retaken by axon terminals and astrocytes, or metabolized by monoamine oxidase (MAO). Homovanillic acid (HVA) is a DA metabolite. The content of central DA is maintained via: (i) regulation of TH activity; (ii) regulation of MAO activity; and (iii) feedback inhibition by catecholamine compounds.

In the CNS, DA mediates a wide range of brain functions involved in motor activities, motivational and sensory information, domestic behaviour, **reproduction** and **coping** strategies to stressful conditions. The actions of DA depend on multiple factors, including the characteristics of its receptors. Two basic receptors, D1 and D2, have been identified based on the characteristics of functions in pharmacological and biochemical mechanisms of signal transduction. All D1 receptors are located on postsynaptic structures, whereas D2 receptors are found on both pre- and postsynaptic structures, and all DA auto-receptors (receptors activated by DA for regulating its self-release from presynaptic terminals) located on somatodendritic sites or on presynaptic terminals are of the D2 type.

Other subtypes of DA receptors have been isolated and categorized as D1-like or D2-like according to their nucleotide sequences and their pharmacological expressions. The D1-like receptors include the D1 and the D5 receptors, whereas the D2-like receptors include D2, D3 and D4. The D1-like and D2-like receptors display differing affinities for the second messenger system in transferring signals. The D1-like receptors activate adenylyl cyclase, whereas D2-like receptors inhibit adenylyl cyclase activity and suppress Ca^{2+} current but activate K^{+} current.

In the CNS, as a neurotransmitter, DA mainly presents in three nerve systems: (i) the dopaminergic nigro-neostriatal pathway, in which dopaminergic **neuron(e)** bodies are located in the *substantia nigra* of the midbrain and send axon terminals to the caudate nucleus-putamen complex (the *neostriatum*); (ii) the

dopaminergic midbrain-mesolimbic forebrain system, where the nerve cell bodies are located in the ventral tegmentum of the midbrain and send axons to the head of the caudate nucleus, the *nucleus accumbens*, the *tuberculum olfactorium*, the amygdaloid nuclei and the cortex; and (iii) the dopaminergic tubero-infundibular system, where the neuron bodies lie in the region of the arcuate nucleus of the hypothalamus and the axons terminate in the median eminence.

Each dopaminergic system has distinctive functions in regulating physiological **homeostasis**. The dopaminergic nigro-neostriatal pathway is involved in the integration of incoming sensory stimuli and regulation of movement (controlling muscle tone and movement). The degeneration of dopaminergic neurons of the nigro-neostriatal pathway is the hallmark of Parkinson's disease, and of several other neurological and psychiatric disorders. The dopaminergic midbrain-mesolimbic forebrain system regulates cognitive, reward, mood, arousal and sensorimotor integration.

Experimental studies show that selective lesions of the dopaminergic neurons of the midbrain mesolimbic forebrain system cause cognitive deficits in rats and primates, especially when the mesocorticolimbic component of the DA is altered. The dopaminergic tubero-infundibular system is involved in neural regulation of the functions of the **hypothalamic-pituitary-adrenal (HPA)** system in response to internal and external stimuli. The endogenous DA secreted in the hypothalamus also exhibits catecholamines' tonic inhibition of luteinizing hormone-releasing hormone (LHRH) release. Administration of exogenous DA also causes a reduction in the LHRH level from the **hypothalamus** and less **luteinizing hormone (LH)** secretion from the pituitary. These effects of DA could have been verified by administration of the DA receptor agonist, 2-Br-alpha-ergocryptine, or blocked by use of DA receptor blocker, haloperidol.

P.187

Although each of the dopaminergic sites has distinctive functions in the regulation of physiological homeostasis, they act in a complicit pattern in the **brain**. The effect of DA on one brain site influences and may even act in opposition to that on another region. It has been indicated that DA activity in the prefrontal cortex can inhibit DA activity in the *nucleus accumbens*. However, acting at the basal ganglia, DA appears to strengthen the capacity of the lower stress-response control centre. Thus, stimulation-induced DA actions are brain region- and their connection-dependent.

Pharmacological studies also indicate that the effects of administrated chemical compounds, such as amphetamine, on physiological and psychological homeostasis are dependent on the brain regions where the interactions between the compounds and DA are conducted. Amphetamine is a reversible inhibitor of MAO, and causes displacement of DA from the storage vesicles into the cytoplasm. Amphetamine acts in promoting activity, such as exploration, at the *nucleus accumbens*, but in the *ventrostriatum* it acts in increasing the tendency to perform stereotypic behaviours.

In particular, as a key neuroregulator, DA affects behavioural exhibition and contributes to behavioural adaptation in response to various stimulations. Disturbance of DA properties has been linked to psychiatric illness such as mood disorders (unipolar and bipolar), social anxiety disorder and **depression**; and dysfunctional behaviours including aggressiveness, stereotypic and compulsive behaviours, as well as changes of cognitive function. Greater concentrations of DA have been found in the brains of Japanese quails with aggressive behaviour.

Alterations in DA concentrations are also linked to stereotyped cage pecking and **feather pecking** in birds. Feather pecking can be reduced by subcutaneously injected haloperidol (a dopamine blocker) and D2 receptor antagonist. Similarly, in the bidirectionally selected Roman high (RHA/Verh)- and low (RLA/Verh)-avoidance rats, increased DA activity occurred in the RHA/Verh rats, associated with increased locomotor activity, a marker of anxiety and stressful status. In addition, experimental stress-induced aggression in mice is associated with heightened levels of DA in the brain. The aggressive reaction can be decreased - facilitated either by DA administered centrally or L-DOPA (a precursor of DA) administered peripherally.

Aggressiveness can also be facilitated by administration of apomorphine, a D2 receptor agonist, but was suppressed by spiperone, a D2 receptor antagonist, and haloperidol and pimozid, both DA blockers.

Dopamine is a potential substrate for synaptic plasticity and memory mechanism in animals. DA-dependent synaptic plasticity plays important roles in an animal's ability to learn to adapt to its environment. In particular, the dopaminergic system and D2 receptors in the medial prefrontal cortex and limbic system are involved in reward learning and appetitive conditioning under both stressful, emotionally unpleasant stimuli and rewarding, emotionally pleasant stimuli. These DA networks are involved in planning, decision making and finalized movement, which may directly or indirectly affect an animal's capability of coping with its environment. Associations between an increase in DA activity and stress-induced unpleasant learning have been found in animals, such as levels of DA correlating with the tendency to develop **stereotypies**.

In contrast, other studies have shown that stress-related learning capacity is preserved after DA depletion in the CNS by cutting the medial forebrain bundle, or following 6-hydroxydopamine treatment. These studies suggest that the role of DA in learning effects is not uniform, which may be related to differences in types of stimuli and duration and frequency of stimulus presentation, such that controllable foot shock but not uncontrollable shock is associated with DA release in the *nucleus accumbens* in rodents. In addition, the differences in dopaminergic and behavioural responsiveness are consistent with the interpretation that coping strategies of animals are based on the inheritance pattern and phenotypic correlations of behavioural, physiological and neuroendocrine variables.

(H-WC)

Double muscling

Double muscling refers to the exceptional muscle development seen particularly in some livestock breeds, most notably Belgian blue and Piedmontese **cattle**, but also in other species such as the Texel **sheep**. It arises as a result of variation in the gene regulating the development of myostatin, which regulates muscle development. Extreme development of the muscles may be desirable from a productivity perspective (increased carcass meat), and it is suggested that the meat from these animals is also more lean, but in some cases double muscling of the rump can be so extreme as to inhibit natural **parturition**. The prevalence of the condition is therefore a cause for concern and, in the case of the Belgian blue, it is estimated that elective Caesarean surgery is used in 90% of cases, due to the frequency of the allele in the population.

(DSM)

Draize eye and skin irritancy test

Based on a scientific paper by John Draize and colleagues (Draize *et al.*, 1944), this test was used, almost without question, until the 1980s to test the irritancy of new chemicals and their formulations. The test consisted of placing increasingly diluted solutions on to the skin or into the eyes of **rabbits** until a dilution was obtained that caused no irritancy. At the same time, the ability of the eye to recover from such an **injury** was determined, a chemical being labelled as 'corrosive' if repair did not occur. Largely due to protests from those in the antivivisection movement, scientists developed a hierarchy of tests that much reduced the animal suffering that undoubtedly occurred, particularly in the eye test. For example, a chemical that showed skin irritancy was assumed to be an eye irritant; chemicals with extremes of pH - being very alkaline or very acid - were not tested but assumed to be irritant and corrosive; and chemicals were tested at high dilutions before more concentrated solutions were applied.

Draught animals

Horses, cattle, donkeys, water buffalo and camelids are the best known draught animal species, but goats, dogs, reindeer,

P.188

elephant, yaks and a few other species have also been important, together with the mule (an interspecific hybrid - the progeny of a male donkey and a female horse). Today, about 400 million animals are used for draught worldwide. Most of these are cattle and water buffalo, whose numbers are increasing while those of working equines have not changed greatly, worldwide. Any agricultural system than can produce more food than is needed to support the human population has the opportunity to keep animals to reduce the physical work people need to do - and to enable tasks to be completed rapidly to take advantage of seasonal weather patterns. A horse eating 4 kg of oats a day can do as much work as ten strong men who, together, would consume nearly 7 kg of grain daily (Smil, 2000).

In history, draught animals have provided large amounts of energy to drive machinery, as well as to work on the land or transport produce. While many of these uses are things of the past, many new functions have emerged. In much of the developing world, growth in transport services is being met by draught animals, especially equids, in both city and country, and the contribution of these animals to assuring national food production and local food distribution is as deserving of attention as that of the animals that work in the field.

Different species have different merits as work animals. Oxen are slow, but at the end of their working life they have a much greater meat value than horses. However, the speed with which horses work is a big advantage, especially in crop cultivation. Technologies have been developed to allow the power of the draught animal to be applied effectively - some technologies are more suitable than others. Poorly fitting harnesses and pack saddles are major causes of suffering, while some otherwise excellent designs for implements and accessories are far too expensive for the developing world. Attitudes towards animals can vary enormously between (and within) human societies, and this can condition the priority placed upon the welfare of draught animals. Within the context of Third World development, it must be remembered that the poorest members of society are too poor to own or to have the use of draught animals. Also, a spread of the use of draught animals into cities could mean that the people who were then responsible for animals may have had no prior experience or family connection with them - and this could prejudice welfare.

Draught animals have an extremely important role to play in world food security. Today's human population is about 6 billion; it is expected to level off at 9 billion by 2050. At present 800 million are undernourished. The major cause of undernourishment is poverty, and improving access to food (food security) depends on a reduction in poverty. Food security is now emphasized more than food production in social policy. It is defined as having access at all times to enough food for an active, healthy life. For country dwellers, food security requires food to be produced locally because of high transport costs and uncertainty of supply. Draught animals clearly have an especially important part to play here. Household

members are often working for wages in cities, and this means labour shortages are frequently a real problem for farmers. In principle, draught animals also have some unique benefits - notably provision of manure. However, in practice, it is now clear that inorganic fertilizer is necessary for large-scale crop production, and considerable labour is needed to spread manure on fields. Draught animals can utilize crop residues, though for adequate work performance a high-energy supplement may need to be fed. For each 1 kg of grain produced there is at least 1 kg of straw, and Smil (1999) calculated that the world's annual harvest of 2750 million t of dry matter was accompanied by production of 3750 million t of crop residues.

The present status of draught animals and their future prospects vary greatly between countries. Essentially, they are a component in the portfolio of strategies available to farmers. Fuel and motor vehicles have to be bought at world prices, and their price and availability will influence the future status of draught animals. So too will the availability of fodder and grazing land. As cropping regimes are intensified and more land is cultivated, less grass and forage will be available, but there will be an increase in crop residues and by-products of food processing. In most countries a range of draught animals is available, and this gives flexibility. Much valuable research has been conducted on such matters as energy nutrition of draught animals, with cattle as the main focus. However, work should also be directed towards neglected species, primarily the donkey, as this species has a definite role in achieving poverty reduction and improving the status of women in some regions.

In principle, there is scope to make draught animals more suitable for their purpose by selective breeding. Many draught horses in particular are defective in conformation, and it would be preferable not to breed from such animals. It might seem an attractive option to bring in animals from elsewhere to improve the breed, but the risk then exists of losing locally adapted genotypes.

Animal **welfare** in developing countries is often poor, and many charities based in the developed world seek to improve conditions for Third World draught animals. Projects are usually designed so that the benefits of improved welfare are tangible and of direct benefit to the owners. Such work often focuses on farriery, the treatment of injuries and veterinary care generally, and the design of affordable and effective harnessing and vehicles.

Dr Hadwen Trust

Dr Hadwen (1854-1932) was a general practitioner in Gloucester, UK, who was concerned by the suffering of animals killed for meat and so became a vegetarian at the age of 21 or 22 - originally taking on a bet from a fellow student that he could not live 6 months without meat. He also claimed that he was in much better health than his carnivorous friends, writing: 'For my part I am quite satisfied with my trial of

Vegetarianism, and it would take more than mortal power to persuade me once again to make my stomach a graveyard for the purpose of burying dead bodies in'. In 1932 at the age of 78, and still active in general practice, he died from a severe

P.189

heart attack. The Dr Hadwen Trust, founded in 1970, was the brainchild of Sidney Hicks, then General Secretary of the BUAV (British Union for the Abolition of **Vivisection**), and the Trust is dedicated to funding exclusively non-animal techniques to replace animal experiments, thus benefiting humans and other animals.

(DBM)

Drinking behaviour

Drinking behaviour is stimulated by the **motivation** provided by thirst, although there may be social reasons for drinking - e.g. it is often observed that grazing cattle move to water at the same time. The reason for this coordination may relate to safety or, in the case of young animals in particular, lack of knowledge concerning the site of water availability. This happens when calves are weaned into yards, and have not previously seen water troughs. Similar scenarios can exist with adult animals in unfamiliar environments. **Psychogenic** polydipsia describes a condition resulting in excessive drinking as some form of **stress** response; and close confinement in a barren environment, e.g. a **farrowing crate**, can result in manipulation of the drinker and excessive water intake. In both of these conditions medullary washout (loss of ability to concentrate **urine** in the kidney) can occur, with serious clinical consequences. Understanding drinking behaviour is of particular importance in the dairy industry, given the high rate of fluid production required by animals, and therefore much research has been undertaken in cattle, but the principles may apply to other species.

The water requirements of animals are met from three major sources: (i) free drinking water; (ii) water contained in feed; and (iii) metabolic water produced by oxidation of organic nutrients. Water in animals is lost through urine, faeces and inevitable evaporation from the body surface and the respiratory tract. Many species experiencing **heat stress** can lose a significant amount of water through sweating, panting and drooling.

It is difficult to quantify total water requirements, which will vary with live weight, health status, physiological state (growth, stage of lactation or pregnancy), level of activity (rate of growth, level of milk production), body condition, coat colour, diet and ration composition, dry matter intake, climatic conditions (ambient temperature, relative humidity, solar radiation and wind speed), management system (e.g. **feedlot** or **grazing**), access to shade and water quality and temperature.

Many animals do not have to drink each day. For example, under mild climatic conditions cattle can go without drinking water for 2 or more days, especially where pasture is lush. However, where water is freely available grazing cattle tend to drink just after sunrise and again late in the afternoon. Generally, more water is consumed in the afternoon than in the morning. Animals usually drink just prior to and after eating, primarily to maintain osmolarity in the contents of their gastrointestinal tract.

The amount of water consumed per day increases as ambient temperature increases. Heat stress stimulates both energy and water metabolism simultaneously. For example, the amount of water consumed by cattle during periods of heat stress is usually greater than the amount needed for metabolism and evaporation. Water intake may be increased two- to threefold during heat stress, and especially when the air temperature is above 30°C. There is a strong relationship between ambient temperature, dry matter intake and water requirements. Feeding concentrate therefore has an important impact on drinking behaviour, dependent on temperature. For example, the water requirements for cattle under various thermal environments are: 2-4 l/kg dry matter intake for temperatures below 25°C; 4-10 l/kg dry matter intake for a temperature range of 25-35°C; and 8-15 l/kg dry matter intake when the

temperature is greater than 35°C. Young farm animals and high-yielding producers (lactating females) also frequently exhibit higher intakes of dry matter per kilogram of body weight, as a result of **concentrate feeding**. They also have a higher water: liveweight requirement, because of increased requirements for growth or lactation. For example, in the 15-25°C temperature range young cattle and lactating cows may require up to 50% more water per day than non-lactating and mature cattle exposed to similar climatic conditions.

Output of water in milk can significantly increase water requirements, and a dairy cow producing 40 l of milk/day may drink as much as 135 l/day under thermoneutral conditions. As with dry matter intake, the relationship with yield is also temperature dependent, so the differential water intake between high and low yielders will be even greater when they are exposed to heat stress. The high-producing animal also has faster dehydration rates due to higher rates of water turnover. Higher water intake is also useful in dairy animals, because the high specific heat of water allows cattle to store heat during the day and dissipate this heat at night.

In hot environments, a major physiological reaction by animals is to increase water intake. This can result in an increase in body water content. As water is lost during a heat challenge a temporary deficit occurs, and increased body fluid mineral concentration stimulates the hypothalamic thirst centre to increase water consumption. However, there may be occasions when animals will not seek water under these conditions, e.g. they may be reluctant to move from shade when there is intense solar radiation. This may result in a reduction in productivity, since a lack of water intake is also associated with reduced feed consumption.

Post-mortem data from cattle that have died from heat stress suggest that dehydration is a major cause of death, even where the cattle have had adequate access to water. Reported lower water intakes for *Bos indicus* than *Bos taurus* cattle may be a function of their smaller body size, dry matter intake and reduced sweating rate. However, there is limited evidence that *B. indicus* cattle can go for longer periods than *B. taurus* without drinking.

Water consumption can be difficult to quantify under field conditions. Total water consumption may be confused with total water usage, and extraneous factors may impact on drinking behaviour to skew consumption. Many species will use water for cooling. For example, horses and cows will dip their heads in water troughs and splash water out of the trough; horses may dunk hay as a matter of routine. Under intensive conditions dominant animals may stand at the water trough during periods of hot weather and block access to lower-ranking animals. Also, in species where drinking behaviour is socially facilitated, inadequate access to water at the same time as others may result in reduced water intake.

The effects of drinking water temperature on water intake are variable. For example, in a hot environment *B. taurus* cattle

P.190

consume more feed and gain more weight when given access to cool water (18°C) compared with non-cooled water (32°C). Furthermore, the intake of cool water is less than of hot water, as cool water produces cooling of the body via contact with the digestive tract. Hot drinking water may reduce the ability to lose heat, and therefore the intake of water may decrease. Provision of shade over drinking stations and placing of pipes below ground will be beneficial in reducing the temperature of drinking water in hot climates. However, if drinking water is too cold intakes may also fall. Under very cold conditions (-10°C or lower), cold drinking water may impair the animals' ability to maintain heat balance and intake will fall. In addition, frozen water will have a major impact on water intake. To overcome this, heated water troughs or bowls may be used for animals in captivity.

Drinking water flow rates into water troughs and bowls can influence the water intake, behaviour and performance of animals. Restricting water flow may result in troughs not filling fast enough to give all animals adequate access to the water. Under these circumstances dominant animals may spend

considerable time at the trough. Others may not have adequate intakes and, as such, are prone to greater production losses. Water quality is also an issue. Water high in salts and other compounds may lead to a reduction in intake. Water with a high soil content and water that looks and smells different from the water the animals are used to may also reduce intake. This could have serious consequences if animals are exposed to heat stress but of limited concern during periods of cold weather. For example, there have been recorded instances where cattle have died from dehydration during periods of hot weather rather than drink muddy river water. High levels of algae in water troughs may also reduce intake.

The type of diet fed and its physical form also affect water consumption. For example, lush green pastures, silage and supplements - such as brewers' grain in the case of herbivores or wet food diets in the case of cats and dogs - will provide considerable amounts of water and therefore result in less water intake. Diets high in protein, sodium and potassium and high in roughage tend to result in a higher consumption of water than those with lower protein and/or lower roughage. It is also suggested that, in some species, diets that are high in silica or dissolved salts will also result in an increased need for water. However, if animals are offered only salty water and salt intake (from feed and water) is high, water consumption may drop, even during periods of hot weather, as the need to balance electrolytes outweighs the need to drink.

In conclusion, drinking behaviour is influenced by a complex interaction of climate, nutrition and the animal. Water systems should be designed to ensure that the animals have access to water as required and that the systems will be able to cope with peak demands.

Drive (drive theory)

Drive, or 'motivational energy', is a concept introduced into motivational and learning theory that is based on the premise that animals are born with innate **needs** that help them to maintain a state of **homeostasis**, and that these needs are met as a result of an internal drive that energizes behaviour towards relevant goals. Relevant stimuli may then guide the behaviour towards these goals but are not considered part of the underlying drive, unless their value is learned through reinforcement. Some make a distinction between a drive, which is defined as the latent energy for a behaviour, and an 'urge', which is a physical expression of this through the ensuing behaviour. Thus the drive builds up and, when the animal acts on this, it has an urge to behave in a particular way. The concept of drive is sometimes invoked to explain the observation that a behaviour may be performed with more vigour when the opportunity arises, following prolonged deprivation. A similar concept in Freudian psychology and some fields of **ethology** is referred to as an 'instinct'.

A key premise of drive theory is that it is the deprivation of the need that motivates behaviour, although it does not necessarily exclude the potential role of stimulus attraction in motivation. As a result the emphasis is on the alleviation of negative emotional states, potentially at the expense of a more balanced consideration of motivation that includes the importance of positive hedonic factors in the regulation and

expression of behaviour (**see: Emotion; Feelings**). Individuals may still eat even if their gut is already full or they are not hungry. In addition, critics of drive theory point out that many behaviours, e.g. resting and sleeping in the absence of other priorities, do not appear to be driven as such.

Drive denotes the internal energy that provides the force, often represented as a mental process, needed to orientate the animal towards the goal that will satisfy its needs. However, further criticism is attracted by this unconventional, confusing and potentially misleading use of the concept of energy as a causal agent rather than as a property of a physical entity.

Both specific drives associated with specific needs and a non-specific drive associated with general behavioural activity have been postulated in the regulation of behaviour. However, it is pointed out by critics that this concept would then seem to demand an almost limitless number of drives to account for all functional behaviours.

Drive may be an inferred state that is not directly observable, but it is suggested that as time passes without the need being satisfied, the drive increases until the goal is achieved through some physical process such as behaviour and the drive/urge reduced. For some, most notably advocates of the psychologists Clark Hull and Kenneth Spence, it is the reduction in drive that provides **reinforcement** for the behaviour and results in learning. However, critics of drive reduction theory argue that many reinforcers neither reduce physiological needs nor do they have a history of association with any such events (i.e. they cannot be considered secondary reinforcers); for example, in the case of babies the focusing of an image may be used as a behavioural reinforcer.

Although advocates of drive theory have proposed a number of amendments to the concept to accommodate some of the criticisms levied at it, critics also argue that the concept is now too vague and imprecise to be useful.

P.191

This term has now fallen out of favour as a scientific context and has been replaced by other motivational concepts (**see: Motivation and Decision making**), although it is still widely used in popular writing to describe behavioural tendencies (e.g. the chase drive of a sheepdog, bite drive of a guard dog, etc).

(LMD, DSM)

Dualism, Cartesian

The term 'dualism' refers to philosophical theories concerning the relationship between the mind and the body. Dualists have maintained that the terms 'mind' and 'body' refer to two distinct entities. Arguments supporting dualism stem from the 17th-century mechanistic concept of science: that facts about the objective world, as revealed by the physical sciences, are not facts about how they appear from any particular point of view, whereas facts about subjective experience are relative to the point of view of an individual conscious subject. The most famous defender of dualism was **René Descartes** (1596-1650), who held that human beings were composed of two substances - material and non-material - but that their essential nature was non-material.

The dualist assumption that the mind is distinct from the body is apparent in various widely used expressions. Thinking about doing something is different from actually doing it. Thinking about mowing the lawn is different from actually mowing the lawn. The former is said to refer to a mental event while the latter refers to a physical action. For the dualist this involves two distinct substances, mind and body, which raises the classical problem as to how the two interact.

Dualism would appear to be intuitively obvious. Whereas the body is a physical structure, and easily identified, the mind is more problematic. Many scientists involved in animal welfare refer to knowledge regarding the animal's physical structure but express scepticism with regard to their knowledge of the

animal's subjective awareness of experience, as well as its motivation. Physical structures can be measured, weighed and are subject to the influence of gravity. Thoughts cannot be measured or weighed, and are free from gravitational influence. This would suggest that the mind occupies an entirely different dimension from physical structures. On the other hand, a physicalist explanation of mental phenomena also has intuitive appeal. Changes in the chemical structure of the **brain**, caused by the intake of hallucinogenic drugs, will influence the kind of thoughts one has. Damage to certain parts of the brain will impair certain mental functions. Instead of thinking of mind and matter as two distinct entities, it is possible to adopt a monistic view and claim that there is just one thing, the brain, that is a physical entity.

Some living beings are said to possess minds, while others apparently do not. Human beings possess minds but the existence of a mental life in many animals is a matter of dispute. Usually, however, the mind is associated with activities involving the body. A being with a mind can engage in conversation, laugh, cry, remember, empathize, deceive, persuade, design, build, solve problems and find a better way of doing things. Mindless things like rocks, trees, dummies and corpses cannot do these things.

Having a mind is bound up with the capacity for intentional activity: rocks and trees may fall, but they cannot jump. Making decisions and carrying them out is a form of intentional activity. Although inanimate objects cannot make decisions there is a sense in which various mammals can be said to choose or make decisions. A dog or a horse may choose not to eat or not to jump over a hurdle. The extent to which this provides evidence of a mental life in these animals is a matter of dispute. There is also a close association between certain forms of intentional activity and moral responsibility. A moral agent is capable of carrying out actions that are influenced by a moral principle. Various animals and inanimate objects may move and cause serious injury, but they are not believed to be conforming to a moral principle and cannot be held morally responsible, and they cannot be said to have a duty to refrain from causing harm.

A major ethical issue is therefore bound up with the question of whether or not non-human animals have some or all of the characteristics associated with minds. In this respect reflections on dualism, on the relationship between mind and body, focus on the age-old philosophical question concerning our relationship to nature: what kind of duties do we have to other beings? For it is clear that we have a different set of duties to beings with minds than to those that do not possess a mental life. We may have a duty not to harm or destroy a plant or an ecosystem, but we have no duty to refrain from insulting it or lying to it. A being with the capacity to reflect is entitled to an apology should we treat it badly, but this obligation does not extend to all living creatures, even though we have a duty to care for them.

Dualists have not, however, provided a satisfactory account of the relationship between mind and body, and behaviourists and materialists have challenged their assumption that mind and body are two separate things. Advocates of behaviourism deny the existence of mental phenomena, insisting that it is simply a question of how bodily and mental characteristics are related. The behaviourist seeks to avoid commitment to two kinds of substance by *reducing* talk about emotions, thoughts, beliefs, desires etc. into complex talk about behaviour. Centralstate materialists attempt to identify talk about mental states with processes in the brain. For the behaviourists and materialists there is no such thing called a mind, hence there is no possibility of dualism and the question of how the mind relates to the body is out of place.

Although the debate between dualists and materialists is centuries old it is far from settled. Questions about minds and the world transcend scientific inquiry involving both metaphysics and ethics; metaphysics seeks the best opinion of what kind of beings we are and what kind of world exists, which raises questions regarding the kind of life we should lead and the scope of our duties towards other beings. Reflections on the nature of mind have a direct bearing on our considerations of the welfare of other sentient creatures. The importance of dualism lies in its acknowledgement of consciousness - and hence a moral conscience - in a modern scientific materialist world view.

In 1641 the French philosopher and mathematician René Descartes published his *Meditations on the First Philosophy*, which discusses the foundations of knowledge, the existence of God and the distinction between mind and body. Descartes established the philosophical foundation for the modern scientific world view, bringing the rigour and certitude of mathematics to philosophical and scientific inquiry. His

P.192

mechanistic view of the universe depicted all kinds of matter as being of the same type, and subject to the same mechanical principles. Cartesian dualism, or 'two-substance dualism', represents Descartes' belief that mind and body are two distinct substances. According to Descartes, knowledge of the mind obtained through introspection carried greater certainty than the sensory-based claims regarding knowledge about the physical world. This belief is a development of his mechanistic standpoint and his sceptical method, which entailed the demand that acceptable scientific truths should emerge from a barrage of doubts and counter-argument. The scientist, held Descartes, should only accept truths that cannot admit the possibility of doubt. Descartes was concerned that a description of the world that relied upon sensory observations was unsatisfactory - as sensations can be misleading - and that a physical description of the world should be based on the certainties associated with mathematics.

In *Meditations*, Descartes employed a variety of strategies to undermine the alleged certainty of sensory-based truth claims. The method of doubt was designed to reject all beliefs whose falsity was conceivable. Descartes invoked two sceptical hypotheses: first, the dream hypothesis - there are occasions when we have thought ourselves to be awake when we were actually dreaming, so how can we be certain, asked Descartes, that we are not dreaming at any particular time, and the objects of sensory experience are illusory? He insisted that it was unwise to trust anything that had deceived him in the past and relegated the claims of sensory observation to a secondary role. This is not to say that Descartes saw no role for empirical studies; his scepticism was directed at philosophical claims that sensory observations could provide the foundations of scientific knowledge. The objection to the dreaming hypothesis is fairly obvious. As an argument designed to demonstrate the inadequacy of sensorily derived knowledge it does not work; we can only discover that the senses have deceived us by invoking those situations where the senses are reliable. The awareness that we had mistakenly believed ourselves to be dreaming is merely derived from sensations we regard as reliable.

His second hypothesis was much stronger, casting doubt on the certainties of mathematical reasoning. It involved the supposition of a 'malignant demon' of the 'utmost strength and cunning' bent on deceiving him every way, with regard to the perception of colours, shapes and all forms of sensory input. Even the principles of geometry and mathematics could have been planted by the demon such that they would be perceived falsely. Thus, having eliminated all possible grounds for certainty, Descartes arrived at one unshakeable foundational statement of truth: the meditator's self-verifying certainty of his own existence, for whatever is doubted the meditator must exist in order to perform the act of doubting. This 'I' is still thinking and existing even when it doubts whether it is thinking or existing. Hence the Cartesian principle, '*Cogito ergo sum*' - 'I think therefore I am'.

The certainty of the *cogito* principle applies only to a conscious being. It marks the foundation of Cartesian dualism; the self-standing truth of the mind's existence has epistemic priority over sensory-based information. Cartesian dualism was to have profound consequences for the status of non-human animals, where the possession of **consciousness** was denied. From the Cartesian standpoint all living beings were analogous to machines. Humans, however, possessed souls and were conscious beings (Descartes did not draw a distinction between the mind and the soul). In contrast Descartes maintained that animals lacked consciousness, could not reason, reflect, participate in discourse and, consequently, like machines, lacked any moral significance in their own right.

Descartes' reflections supported the emerging 17th-century scientific consensus which held that humans, who have the capacity to reason, use **language** and construct mathematical schemes, reveal a mental life independent of their physical nature, whereas other animals are wholly lacking in mind are akin to

mechanical automata. Animals were, like objects, morally significant because they were valuable to people. The Cartesian tradition of treating a vast range of living phenomena as machines, incapable of any awareness of **suffering**, was scientifically attractive and marked a departure from the medieval view that animals were natural servants of mankind. Many of Descartes' followers employed this doctrine to justify what is now perceived as the infliction of enormous suffering on animals in the name of science.

Critics of Cartesian dualism have pointed out that the postulation of mind and body as two incompatible substances prohibits an explanation as to how they allegedly interact. Descartes speculated that the point of interaction was the pineal gland, located in the brain. But as this is a material substance it cannot represent the point at which the non-physical mind and the physical body interact. Problems also arise with regard to mental attributes, such as sensory awareness. Most animals are aware of hunger, thirst, pain and so on, which, based on a purely Cartesian model, would have to be denied to most animals.

Cartesian dualism is not the dominant theory in contemporary philosophy of mind where physicalist alternatives predominate. Two-substance dualism is frequently dismissed as the doctrine of the 'Ghost in a Machine'. It is also maintained that the possession of mental functions is a matter of degree, rather than an 'all or nothing matter'. But the Cartesian legacy of separating mental and physical functions, with the latter wholly explicable in mechanical terms, laid the foundations for the modern scientific approach to medicine and animal research.

Dust bathing

Dust bathing is an important maintenance behaviour that consists of tossing and rubbing dust into the **feathers** or fur to maximize contact between dust and feathers or skin. It is found in a number of species of bird, particularly the Galliformes, and is observed in a number of species of mammals, such as **horses**, baboons and desert **rodents**.

P.193

In birds, the behaviour begins with the appetitive phase, during which the individual scratches and pecks at the ground, often forming a shallow hollow. Following this is the consummatory phase, in which the bird lies on its breast, fluffing up its feathers, a process referred to as tossing. This consists of sequences of leg scratching, bill raking, head rubbing and vertical wing shaking, which cause the dust-bathing substrate particles to penetrate the feathers and come into contact with the skin. This behaviour is followed by rubbing, in which the bird lies on its side, feathers are flattened and the wings are pressed against the body, accompanied by side and head rubbing, which result in an increase in contact between the substrate and the downy part of the feathers and the skin. In the final stage of dust-bathing behaviour

the bird may stand and perform body and wing shaking, which functions in removing the substrate from the feathers.

The majority of studies of dust bathing have focused on laying hens or quail. Adult hens, when provided with a suitable substrate, tend to dust bathe approximately every other day, with the average bout lasting approximately 30 min. It is a behaviour that shows a **circadian rhythm** and tends to occur mostly during the middle of the day or when conditions are otherwise warm and bright. It has been suggested that it is a behaviour that may be socially facilitated, as hens in a group often synchronize their dust bathing. This may, however, be due to the shared presence of external factors, such as heat, light and a suitable substrate, that initiate dust-bathing behaviour. Among mammals, the frequency of dust bathing varies according to species and the function of the behaviour.

Studies have demonstrated a variety of functions of dust bathing among different species. Examples include **communication** and marking, **courtship behaviour** and **thermoregulation**. However, in birds, dust bathing appears mainly to function in maintaining good feather and skin condition, through the removal of stale and excess lipids that have been applied to the feathers from the uropygial gland. This removal of stale lipids functions in improvement of feather quality, necessary for a number of reasons such as thermoregulation, flight performance, camouflage or attractiveness to potential mates. The barbs of the downy part of the feather stick together with the build-up of stale lipids. Dust bathing in a suitable substrate reduces this and causes the downy part of the feathers to appear fluffier. Because fluffy down is a good insulator, dust bathing may save energy by preventing heat loss caused by poor feather condition. Different substrates are thought to vary in their effectiveness at removing excess lipids. For example, it has been shown that, following a period of litter deprivation, hens on wood shavings spent more time dust bathing than those on sand, but the removal of lipids was the same, suggesting that wood shavings may be less effective at lipid removal and that birds must dust bathe for longer in order to achieve the same effect. This is likely to be a result of litter particles of differing sizes reaching different areas of the feathers.

One additional possible function of dust-bathing behaviour is the removal of **parasites**. It is possible that the dust-bathing substrate acts to suffocate or desiccate ectoparasites, or even physically remove them from the skin and plumage. In addition to this, a number of ectoparasites are known to be attracted to lipids, and so the removal of excess lipids may help in controlling such parasites. There is, however, little experimental evidence to support this theory as a function of dust-bathing behaviour.

There does not appear to be a particular '**sensitive phase**' during which preference for a dust-bathing substrate is established. Provided adult hens have previously encountered a suitable substrate for a brief period at any point during rearing, they will readily accept it for dust bathing as adults. Naive chicks initially show no preference for any of a variety of substrates, and can be trained to dust bathe on apparently suboptimal substrates such as straw or feathers. Birds will, however, show clear preferences for certain substrates over others. Studies have shown that, when given a choice, chicks show a preference for peat or sand over woodshavings, feathers or straw. Such preferences may well reflect the relative effectiveness of different substrates at removing stale lipids.

Dust-bathing behaviour appears to be strongly internally motivated, and birds that have been prevented from dust bathing show a marked **rebound behaviour**, displaying increased dust-bathing activity. Studies have shown that hens have a strong motivation to gain access to a litter substrate, and will work to gain access to a suitable substrate for dust bathing. It is likely that litter deprivation in birds may result in reduced welfare through the prevention of dust bathing, as well as other litter-related behaviours such as **pecking behaviour** and scratching. Motivation to perform dust bathing continues to exist, even when the behaviour is apparently functionless.

Caged hens, housed on wire flooring lacking a suitable loose substrate, will readily go through the sequence of behavioural elements of dust bathing on the wire floor. This has been described as a **vacuum**

behaviour, although this is not entirely correct, as birds tend to perform this behaviour near to the feed, flicking the feed on to themselves as a substrate. This behaviour is better termed 'sham' dust bathing, and does not appear to affect motivation to perform real dust bathing if given the opportunity. Similarly, featherless hens have also been shown to dust bathe, and also show an increase in dust bathing following deprivation.

Dust bathing is a highly important behaviour to many Galliforme species of bird, and one that is shown to be performed by captive birds even in the absence of its functional consequences (removal of stale lipids). It is likely that, in conventional battery cages or furnished cages that lack a suitable dust-bathing facility, the **welfare** of laying hens may be severely compromised.

Dynorphin

Dynorphins are a class of naturally occurring **opioids** that are found throughout the **central nervous system**, but in highest concentrations in the **hypothalamus**, medulla, *pons*, midbrain and spinal cord. They are produced from prodynorphin, which is cleaved by proprotein convertase 2 (PC2) to give dynorphin A, dynorphin B and α/β -neo-endorphin. Sometimes this processing is incomplete, resulting in the release of a conjoined dynorphin A and B molecule known as 'big dynorphin'. Dynorphins act primarily through kappa (κ)-receptors, but also have some affinity for mu (μ)-, delta (δ)- and bradykinin receptors.

P.194

Dynorphins are produced in a number of different areas of the CNS, and their function is somewhat dependent on the site of production. As with other endogenous opioids, dynorphin is implicated in the **pain** response, being analgesic and being six to ten times more potent than morphine when applied to spinal cord κ -receptors. However, it may also have a pain-inducing effect via bradykinin receptors.

With relevance to the animal **welfare** field, dynorphin has been implicated in **stress**, **exploratory behaviour** and **depression**. Imposed stressors in rodents, such as forced swim tests, foot shocks and immobilization, have been shown to elevate dynorphin A and B in the hippocampus. Exposure of rats to novelty also induces an increase in hippocampal dynorphin B, and the concentration of dynorphin B is negatively correlated with exploratory behaviour. Increased dynorphin within the *nucleus accumbens* is also implicated with **learned helplessness** - an animal model of **depression**. In pigs, decreased levels of κ -receptors in the frontal cortex have been associated with high levels of oral **stereotypic behaviour**, potentially as a result of down-regulation in response to high dynorphin levels in the brain. Sows housed long term in close confinement have been shown to have higher levels of dynorphin in the frontal cortex compared with group-housed sows, with correspondingly higher levels of stereotypic behaviour and inactivity, which has been suggested as being akin to learned helplessness seen in rodents.

Dynorphin has also been shown to play a role in: (i) **appetitive behaviour**, with high levels increasing appetite; (ii) **thermoregulation**, with high levels shifting the body towards hypothermia; (iii) addiction, with high levels in the *striatum* and *substantia nigra* in response to repeated exposure to cocaine; and (iv) **circadian rhythms**, with high levels in the **pituitary gland** and low levels in the hypothalamus during the day, and the reverse during the night.

Echolocation

Echolocation (also known as biosonar) is the use of the reflection of pulses of high-frequency sound waves by an individual to help it orient itself as it moves through the environment. The source direction of higher-frequency sounds is more readily detectable, and the use of very short pulses allows precise calculation of the distance of physical objects that reflect the sound. Thus individuals can potentially gain good resolution of physical objects in their environment (including prey) that they may not be able to see. Echolocation was first identified in bats, but is also used by some species of cave-dwelling birds (e.g. the cave swiftlet), nocturnal birds (e.g. oilbirds), terrestrial mammals (e.g. shrews and tenrecs - an example of **convergent evolution**) and marine mammals (e.g. toothed whales, including the dolphin and porpoise).

(DSM)

Ecological niche

The meaning of the term 'niche' has a long and somewhat winding history. Grinnell originated the concept in an obscure paper in 1914, and then developed it during the next decade with particular application to birds and mammals. Wholly without reference to Grinnell, Elton in 1927 devoted an entire section to niches in his influential book *Animal Ecology*. Consistent with its then prevalent figurative usage as a 'recess', both authors considered the niche as a place or role in the ecological community and sought to understand the existence of ecological equivalents - species that have similar ecological characteristics in different communities. Both authors included species' relations to food resources as well as to predators. Both included spatial aspects, mainly at the finer scales, to describe such relations; these scales extended to coarser values for Grinnell. Elton sometimes included a set of species in a single niche. Mostly, however, the concepts presented by Grinnell and Elton were very similar.

Hutchinson revolutionized the meaning of ecological niche in 1957 by focusing on the occupant rather than the recess or role, thereby allowing the niche to change as a function of the other species in the community, especially as affected by resource competition. Hutchinson phrased his concept quantitatively as a set of resource ranges along multiple dimensions, forming a hypervolume within which a species population could survive (Hutchinson niche). Such a hypervolume would typically be difficult to ascertain empirically and, perhaps for that reason, MacArthur and Levins in 1967 defined the niche as a utilization distribution giving the fraction of resource use for a species population - e.g. the percentage of foods of different sizes eaten by the population as a whole, as determined by sampling the diets of representative individuals.

The utilization distribution extends to as many resource dimensions as are useful; Fig. E.1 illustrates a one- and two-dimensional resource utilization distribution. Utilization distributions were much easier to determine empirically than the data on population growth needed for Hutchinson's concept and, indeed, ecologists had been gathering such data for years in studies of resource partitioning (see below). Finally, something of a revival of Hutchinson's niche concept was developed in the 1990s by Chase and Leibold, culminating in a recent (2003) book. These authors used population-dynamical theory to delineate those

values of resource density taken jointly (each resource is plotted on a separate axis, as in Fig. E.2a) for which a species population has a zero or positive population growth rate, those values being defined as its niche. Unlike Hutchinson's concept, axes were not limited to resource kinds, but also included predators as well as physical stresses (see Fig. E.2b, c, d). While exciting as a theoretical concept, the Chase-Leibold niche has the same disadvantage as Hutchinson's in that it could be difficult to determine in nature, especially for large organisms having many food species; it is probably most practically applied to microcosms - communities of necessarily small species in experimentally contrived containers.

The utilization-distribution concept is perhaps the most useful of the three for those working with vertebrates, and ecologists have focused on three of its properties: niche axes; niche width/breadth; and niche overlap.

First there are the *niche axes*. The possible axes or dimensions of an ecological niche can be classified into three broad types. First, habitat (or place) dimensions specify where a species is found, and can range from fine-scale (called microhabitat), such as feeding height in a tree or perch diameter, to broad-scale (called macrohabitat), such as vegetation zone. A species' foraging behaviour results in a utilization distribution over a set of habitat categories and, in turn, implies a characteristic set of prey eaten from each. Secondly, food-type dimensions specify characteristics of the food items themselves, e.g. size or hardness. Figure E.3 gives an example of the food-size niche for five tern species. Thirdly, time dimensions specify when individuals of a species population are active; time can be daily or seasonal. The former especially reflects behaviour, e.g. in some species individuals favour early and late times while other species have individuals active at midday. Frequency histograms of percentage activity by hour or by month can be used to represent the daily or seasonal time niche, respectively.

The second property, *niche width/breadth*, describes the degree to which a species' utilization is widely spread over a set of resource categories (generalized) versus concentrated on a few (specialized).

Typically, niche width is measured as the

P.196

standard deviation of the utilization distribution. In Fig. E.3, the species of tern at the top has the greatest niche width, while that at the bottom has the smallest niche width. The greater the niche width, the more generalized the species, while the smaller the niche width, the more specialized it is. Ecologists also measure niche position as the average or mean of the utilization; in Fig. E.3 the more robust the beak of a species, the more to the right is its niche position (i.e. the greater is its mean food size). Often there is a positive correlation between niche position and niche width for arithmetic prey categories; were log prey size to be used instead, the positive relation would be substantially reduced.

Fig. E.1. The ecological niche as a utilization distribution. (a) A one-dimensional niche, where the dimension is prey size. Numbers refer to prey-size categories, indexed by b . (b) The same utilization smoothed; (c) a utilization for two resource dimensions, prey size and feeding height (after Schoener, 1989).

The niche axis approach is limited to types of niche properties that can be ordered along an axis, i.e. those that are quantitative. However, qualitative categories, such as prey taxa, can also be used; then niche width is measured as the diversity of fractional use over a set of these categories, e.g. as:

$$H' = \sum_{i=1}^S p_i \log p_i$$

where p_i is the fractional use of resource category i . With such a measure, a species eating relatively evenly over a set of prey taxa would have a greater niche width than one concentrating on only a few taxa.

The third property, *niche overlap*, results from resource partitioning studies, those documenting differences in the utilization niche between species occurring in the same general area. Species have been found to differ commonly in habitat, somewhat less commonly in prey type and least commonly in time (perhaps because the latter does not result in as great a difference in the resource populations being utilized). But how different must the niches of species be in order for them to

P.197

coexist, i.e. for one species not to be eliminated by competitive exclusion? This can be studied using niche overlap - the degree to which two utilization distributions overlap. Under certain assumptions about the existence and nature of competition, the greater the niche overlap the less likely it is that the species can coexist. That degree of niche overlap just allowing coexistence is called the limiting similarity; any greater overlap would eventually result in competitive exclusion. Limiting similarity is measured in units of d/w , where d is the distance between the niche positions of two species and w is the standard deviation (d is divided by w because, for the same d , the larger the w , the larger the overlap).

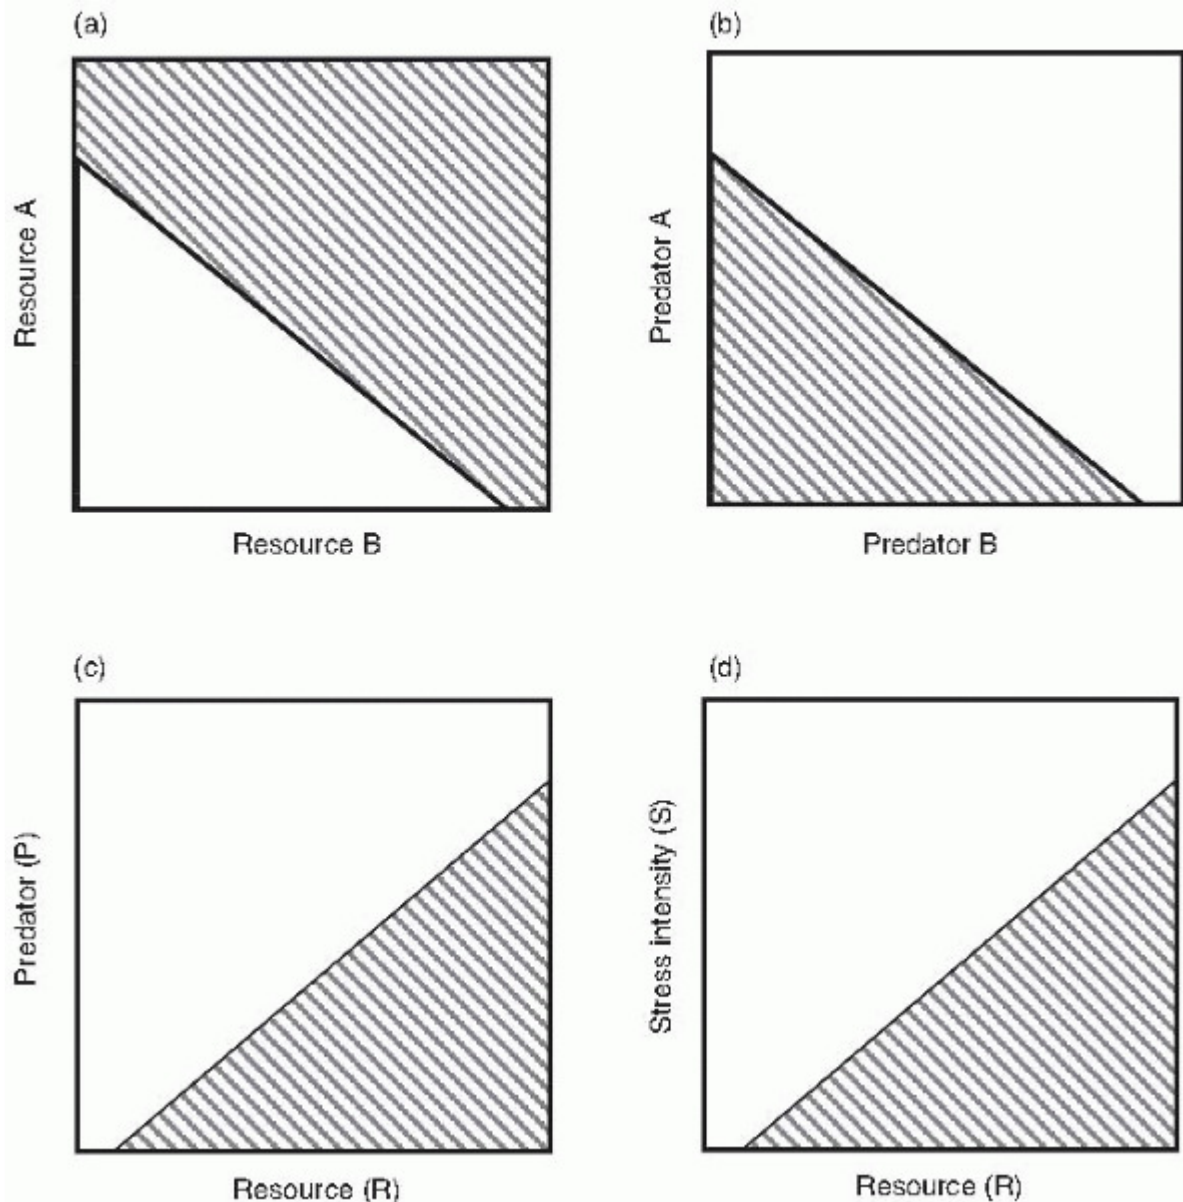

Fig. E.2. Examples from four modules of the requirement component of the niche for a species interacting with two limiting factors. The zero net growth isocline (ZNGI), where $dN/dt = 0$ (thick solid line) denotes the boundary of the species' niche (birth rate = death rate). Shaded areas are where birth rates are greater than death rates, and are included within the species niche. (a) A species with two substitutable resources, A and B; (b) a species with two predators, A and B; (c) a species with a predator (P) and a resource (R); (d) a species with stress (S) and a resource (R) (modified from Chase and Leibold, 2003).

Some species, such as the particle-feeding gastropod *Hydrobia*, show a substantial difference in utilization distributions of food sizes when occurring together, but take about the same food sizes when occurring in a solitary state. Differences in utilizations (niche differences) are reflected in differences in phenotypic distributions, in this case body size. The appropriate phenotypic trait is called an indicator for the niche;

another example is beak size for food size in the terns of Fig. E.3. Vertebrates sometimes show quite regular differences in phenotypic indicators, even where there is a rather large number of coexisting species. Thus felids and mustelids show extraordinarily regular phenotypic spacing when the diameter of the canine is the indicator.

(TWS)

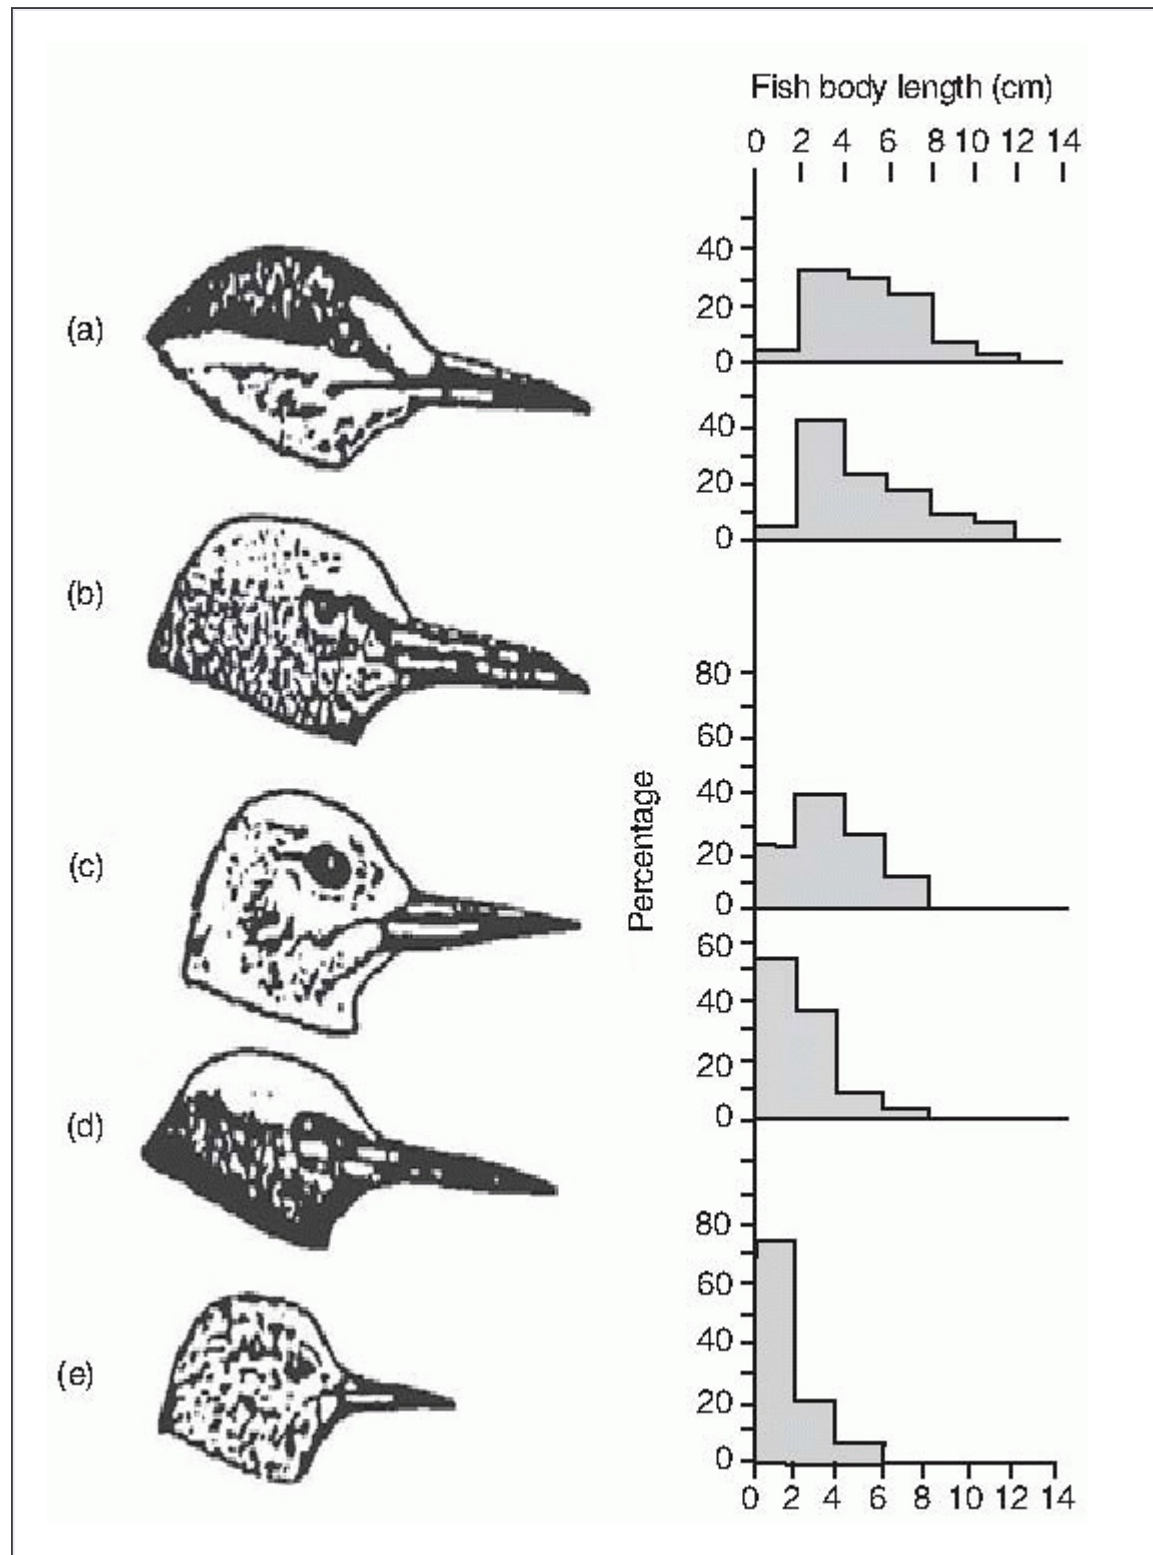

Fig. E.3. Utilizations for five species of tern on Christmas Island, as studied by Ashmole. Niche axis is food (fish) length. Ecology

Ecology is the scientific study of the distribution and abundance of organisms, and how those organisms interact with each other and with their environment, which includes both living (e.g. competitors for food) and non-living (e.g. atmospheric nitrogen) components. Ecology relies upon and builds upon natural

history, the careful observation and description of natural phenomenon but, as a science, ecology seeks to explain those observations in a way that allows extrapolation to novel situations.

Ecological questions often cannot be addressed in the same way that scientists would address other types of questions. In hypothetico-deductive scientific enquiry, carefully designed experiments are conducted so that empirical data can be used to reject alternative hypotheses until only one likely explanation is still plausible. However, in ecological research there are often too many uncontrollable variables for rigorous control and experimentation, so variables may interact in ways that cannot be detected through a reductionist approach. In addition to methodological concerns, the ecological question of interest may in fact not be *whether* factor A plays a role in producing observation B; the important question may ask *how much* influence factor A has on observation B, and whether this influence is the same across all levels of factors C, D, and E. One example of an ecological question not easily amenable to traditional hypothesis testing is the question: 'Under current governmental regulations, how will polar bear reproduction be affected by noise associated with petroleum extraction?' However, this type of question can be addressed with mathematical models built upon the answers to questions such as: 'What is the hearing range of female polar bears?'

Ecology is a historical science; current patterns and processes have been shaped by **evolution**, past stochastic events and ongoing responses to current conditions. For example, the distribution of the cattle egret has changed dramatically since its colonization of North America several decades ago, but that colonization would not have been successful without traits the egret possessed due to past natural selection. As a consequence of egret colonization, current survival rates of some North American grasshoppers may now depend on whether past predation by other bird species has shaped grasshopper anti-predator behaviour that coincidentally thwarts hungry egrets.

Ecologists study questions at various levels of organization and complexity, from broad enquiries spanning the entire biosphere (e.g. the water cycle) to enquiries that focus on individual organisms (e.g. the **seasonality of reproduction**). Each level of organization exhibits properties not apparent at lower levels of organization, but dependent on characteristics of those smaller units (e.g. genetic differences among neighbouring populations can be influenced by dispersal of individuals). Ecologists sometimes consider the operation and impact of small-scale factors on individuals, but ecologists typically focus on questions regarding larger scales - individuals, populations, communities and ecosystems. A population is the group of potentially interbreeding individuals of the same species. Population ecologists seek to understand the factors determining the rate at which individuals are born, reproduce and die, and how changes in those rates alter the size of the population. An ecological community is comprised of the populations of different species that interact with each other in a particular habitat. Community ecologists seek to understand interactions between species, species diversity and persistence and community productivity. Landscape ecologists strive to understand the spatial and temporal heterogeneity of communities, while ecosystem ecologists investigate the interactions of communities of organisms and their abiotic environments.

An ecologist might specialize in using certain methodologies to address questions (e.g. molecular ecologists) or focus on

P.199

specific types of each level of organization (e.g. freshwater ecologists). Although many subdisciplines of ecology have relevance for applied animal behaviour and welfare, several subdisciplines are particularly relevant. Agroecologists apply ecological knowledge in the development of sustainable agricultural practices, including animal husbandry. Conservation ecologists strive to restore and maintain long-term functional levels of **biodiversity**. Disease ecologists attempt to understand and control the factors contributing to the spread of diseases. Ecotoxicologists endeavour to identify and minimize the impact of chemical and biological pollutants at various ecological levels, including the physiology of individuals. Sensory ecologists investigate the way in which animals receive and respond to information about their

environment, which may guide human efforts to maintain species-typical psychological, physiological and reproductive processes in a captive or domestic setting. Urban ecologists seek to identify how human cities alter ecological processes: the preservation and restoration of undeveloped habitats; the degree to which those habitats are connected; and the levels of environmental pollutants that determine which species persist in urban areas. Wildlife managers traditionally focused on the management of populations of **free-ranging animals** for sustainable human consumption, but now utilize population and habitat management for the broader conservation of biodiversity.

As an example of the application of ecological principles, consider the alteration of carrying capacity in the conservation of eastern bluebird populations in North America. The carrying capacity for an organism is the population size that can be sustained in a given patch of habitat. The ecological factor(s) limiting an animal's carrying capacity may be food, water, shelter, refuges from predators or breeding sites. Modifying the factor limiting the carrying capacity can be one way to alter a population's size, for better or worse. Populations of eastern bluebirds increased dramatically as native forests were converted into fields suitable for bluebird foraging adjacent to wooden fences providing nesting cavities. Through the early 1900s, however, competition with introduced competitors for nesting cavities, replacement of wooden fences with metal fences and pesticide use reduced the carrying capacity and populations of eastern bluebirds. Subsequent widespread installation of thousands of birdhouses designed specifically for eastern bluebirds increased carrying capacity throughout large areas, which resulted in rebounding bluebird populations.

From an applied standpoint there is increasing recognition that, although ecology developed from a descriptive field into an explanatory field, ecologists must now also predict how organisms will fare under conditions that ecologists have never seen and organisms have never experienced. Human activities such as **hunting**, fishing and farming were made possible by the types of observations that underlie ecology; the ongoing challenge for ecologists is to understand and address the ecological ramifications of increasing human resource use.

Economics of behaviour

Economic theory can provide a beneficial tool for the study of animal preferences and welfare. By applying economic models and techniques to animal behaviour, we can infer the value that animals place on particular behaviours or resources, which is a fundamental key in assessing animal welfare. Methods based on economic models have been used to assess the value that various species place on a number of different resources. For example, experiments have investigated the value of **dust-bathing** substrates, or nestboxes for hens, social contact for pigs and various **enrichments** for laboratory mice and mink.

Common assumptions

Although there are some differences between human economics and animal behaviour, the similarities are sufficient to allow us to draw comparisons in a range of behavioural disciplines such as behavioural ecology, operant psychology and animal welfare. In all cases we are interested in the choices being made by a subject, whether a human in a supermarket, a plover in a field or a rat in a **Skinner** box. Although the decision-making processes of humans and other animals may be quite different from one another, the assumptions made in the models show enough areas of agreement to justify the drawing of parallels between economics and animal behaviour.

In both cases it is assumed that the consumer is rational. 'Economic man' is assumed to choose the best possible combination of resources under all circumstances, his primary motivational principle being the attainment of an optimal state (Lea, 1978). The assumption of rationality among consumers means that each consumer approaches each buying decision with a blank, unbiased mind, and then rationally considers all the available options. One of the basic tenets of behavioural ecology is that natural selection will shape animals' behaviour so as to maximize their inclusive **fitness**. Natural selection should therefore design animals' decision-making processes so as to allow them to make the most cost-effective choices between different options, which will minimize the cost:benefit ratio of the behaviour.

Some other logical assumptions, which were originally proposed for human models of **preference**, also apply to animal systems. The first is known by economists as two-term consistency. This means that if resource A is sometimes chosen over resource B, but resource B is at other times chosen above resource A, the consumer is indifferent in choosing between resources A and B (Varian, 1997). This supposition is taken a step further with the assumption of three-term consistency, or transitivity of preference. If preferences are transitive, as models of choice behaviour assume, then if the consumer prefers resource A to resource B, and resource B to resource C, then resource A should be preferred to resource C.

So the assumptions of human economics and animal behaviour can be seen as analogous. In human economics we

P.200

assume that the consumer makes rational decisions based on perfect knowledge of the market; and in animal behaviour we assume that natural selection has shaped animals' decision-making processes such that they make optimal choices.

Economic models of choice

Simple economic models are descriptive, and describe the different choices that a consumer can make within the constraints of a particular budget; more complicated models can be used to compare demand between very different goods or resources to determine consumer preferences between the different choices available.

Budgets

The budget constraint on a consumer describes the total amount available to spend. For two resources, x and y , there are various combinations ('bundles') of amounts of the two resources that a consumer can buy. A budget line can be drawn by joining all the bundles that the consumer can afford, as shown in Fig. E.4.

In Fig. E.4 m/p_1 is the amount of good 1 that a consumer could buy if all his money was spent on good 1, and m/p_2 is the amount of good 2 that could be purchased if all the budget was spent on good 2. If the income of the consumer or the price of either of the goods changes, then the budget set will also change.

Budget sets and constraints can also apply to animal behaviour. In this case, time and energy are usually assumed to be the currencies with which the animals are working. In some species, or at certain periods during an animal's life, one or the other of these currencies may become dominant in determining behaviour. Short-lived species such as butterflies that have a limited time to mate before dying are likely to be more restricted by their time budget than by energy constraints. Foraging bees, though, are limited by the energy constraints of flight. If time and energy are considered as currencies in an animal's budgets, then it is easy to see how their budgets could be changed in ways similar to those of humans. An increase in the day length of a diurnal species could have the effect of increasing income (and therefore budget), as could an increase in the energy value of the animal's food source. Changes in the price of goods can be likened to changes in the ease of executing a particular behaviour pattern, such as finding and exploiting a food source, which could affect the time and energy remaining available to the animal.

Budget sets can therefore be constructed to describe animal behaviour options, and provide a useful basis from which to start investigating the influences on an animal's behaviour. The mechanism by which the consumer actually decides upon one of these options is not described by this simple model, but can be analysed economically by creating more elaborate models of consumer choice.

Utility

The relative value of a particular chosen bundle of goods can be labelled by assigning it a utility value. The better bundles in a budget set are assigned higher utility values than less ideal bundles. The magnitude of the difference is of no significance, as the relative utility is deduced simply by the position of the bundle in the list. In animal behaviour, utility is commonly used by behavioural ecologists, who use its analogue, fitness, to describe the relative advantage of behaviours or resources to the animal. For domestic animals, fed and protected by humans and often killed when young, the evolutionary consequences of behaviour have become divorced from the proximate need to carry them out (Dawkins, 1990). This means that animal welfare researchers place more emphasis on what the animals want to do than on the ultimate fitness consequences of their choices. Attention has therefore rested on determining the preference for bundles rather than speculating about the evolutionary advantage of choosing them.

Preference and indifference

The preferences that a consumer shows for certain goods or bundles of goods are most simply described by presenting them graphically. For any particular bundle (e.g. x_1 , y_1) on a graph, we can identify all the bundles that the consumer prefers: all the bundles on the boundary of this set are the bundles between which the consumer is simply indifferent (x_1 , y_1) (Fig. E.5; Varian, 1997). This boundary line is the indifference curve for that bundle. Different curves are, by definition, different levels of preference for the bundles of goods, so bundles that offer more of the goods will be higher and to the right of less preferred bundles.

Optimal choice and consumer demand

Indifference curves give us information about the way in which the goods on offer are perceived by the consumer, but still do not help us determine which bundle the consumer will regard as the optimal choice. In order to develop a model of a consumer's optimal bundle choices, we need to integrate the budget set of the individual with the indifference curves for the resources in question. Because consumers will always choose the most preferred bundle they can afford, we can determine the optimal choice of a consumer if we know the consumer's budget and the indifference curves for the goods. The optimal

P.201

bundle is usually the point at which the indifference curve is at a tangent to the budget line, as described in Fig. E.6.

All the points on line A would be preferred to any on the other two lines, but they are beyond the consumer's budget, represented by the dotted line. The points on B are preferred to any on C because B is the higher indifference curve, but only one point on B intersects the budget line, so this is the optimal choice for the consumer - the best possible bundle the consumer can afford. When prices or income change, however, the optimal choice for the consumer will also change. The consumer's demand function is the mathematical function that relates optimal choice to different prices and incomes. The function $x_1(p_1, p_2, m)$ describes the relationship between the quantity of the good demanded (x_1) and all the factors that will influence the demand for the good, namely its price (p_1), the price of all other goods (p_2) and the consumer's budget or income (m). It can be derived either by holding income constant and altering the good's price or by holding price constant and altering the consumer's income, and plotted graphically as in Fig. E.7.

Demand curves typically have negative slopes because, as the price of a normal good increases, the demand for it will decrease (Varian, 1997). They give information about the responsiveness of the consumer to changes in price or income but, to make meaningful comparisons between goods that are not on offer in the same bundle, we need to subtract measures such as elasticity, consumer surplus and reservation price from the curve.

Price elasticity

Elasticity is expressed as the ratio of the price to the quantity bought, multiplied by the slope of the demand function. The price elasticity of demand is defined as:

$$\text{price elasticity} = \frac{\text{change in quantity demanded (\%)}}{\text{change in price (\%)}}$$

By using percentages or ratios, the units of price and quantity are eliminated, so comparisons can be made between different goods. The sign of elasticity of demand is usually negative, because for normal goods the amount demanded will decrease as the price increases, although conventionally the minus sign is often dropped in verbal discussion of demand.

Income elasticity

Income elasticity is very similar to price elasticity, but describes changes in demand with changes in income or budget rather than prices of individual resources. It is defined as:

$$\text{income elasticity} = \frac{\text{change in quantity demanded (\%)}}{\text{change in income (\%)}}$$

For normal goods, the amount bought will increase as income increases, so they have positive income elasticities.

P.202

When a demand curve is plotted on log-log coordinates the curve becomes a line, and the resulting function of this line takes the form of $Y = aX + b$, where Y is the log of quantity purchased and X is the log of the price. On such lines, the slope, a , is the elasticity coefficient (Varian, 1997). The more a resource is influenced by price or income, the greater the elasticity.

Consumer surplus

The area bounded by a demand curve is called the consumer surplus (Ng, 1990; Varian, 1997) and is used by economists as a measure of the utility of a good or service when assessing human welfare. It has been

suggested (e.g. Ng, 1990) that this would be a more valid way of measuring the welfare value that animals derive from resources than using elasticity of demand. Resources for which larger consumer surpluses are displayed are viewed as more important than those with a smaller area beneath the curve.

Maximum price

The maximum price that a consumer is willing to pay for a resource or service can be used to assess the value of the first obtained unit of a particular good. This measure is sometimes referred to in economics as willingness to pay, or reservation price. A higher maximum price would indicate that the consumer places a higher value on obtaining a unit of this resource. This, too, could therefore draw useful information from demand curves about the welfare benefits of a good (Mason *et al.*, 1998).

Economic analogies in animal behaviour and welfare

The assumptions of economics and the evolution of behaviour discussed above are similar enough to justify the adoption of economic techniques for use in animal behaviour studies. Economists may be interested in what particular goods a person will buy, and how these decisions will be affected by a change in the price of the good or the amount of money the person has to spend. In a similar way an ethologist may be interested in what behaviour an animal will carry out given a number of options, and how this decision will be affected by time or energy constraints. However, the aim of animal welfare studies is to extrapolate further than this, so it is assumed that, if one behaviour is chosen above another, this is not just better for the animal in terms of its inclusive fitness, but also that its importance carries some more proximate benefit to the animal. For such studies, the utility or value of different behaviours or animals' motivation to perform them is determined from measures of preference or quantified using consumer demand measures, and these are used to infer the degree of welfare benefit of providing these different opportunities.

Animals' budgets can be experimentally manipulated, e.g. by altering the energy available from their food. In animal behaviour resilience, which is the extent to which particular behaviours are performed when animals' time budgets are reduced, is a type of income elasticity. The price of individual resources or of performing particular behaviours can be altered by imposing a cost, e.g. pressing levers or pushing weights, before the animal can access them. The number of times a cost is paid or the time spent paying the cost can be taken as a measure of consumption, and demand curves can therefore be constructed from which the various measures of resource value can be taken.

Dawkins (e.g. Dawkins, 1990) first introduced this method of assessing the importance that animals place on resources or behaviours. By reducing hens' time budget, their demand for litter in which to dust bathe was compared with demand for food, a resource of known importance. Since then, the slope of the curve has been the most frequently used measure of value (e.g. in pig, hen, calf and mouse studies). Some authors (e.g. Ng, 1990) have challenged this, advocating consumer surplus and maximum price instead, and some researchers have adopted these techniques. There have also been considerable differences in the way in which these experiments have been designed (e.g. whether or not the subjects are allowed to control their own bout lengths after paying for a behaviour). However, commentaries on the design of such experiments (Ng, 1990; Mason *et al.*, 1998) have helped to clarify which methods will provide the most valid results. Provided that the animals' behaviour conforms to the economic assumptions, and that the experiments are carefully designed (Mason *et al.*, 1998), such techniques have considerable potential for evaluating animal welfare.

Ecotourism

Ecotourism is tourism in which the main attraction is the natural environment and which tries to teach some **ecology**, minimize environmental impacts and contribute to **conservation**. Wildlife is a major component of many ecotourism products. Ecotourism can be both a tool and a threat in wildlife conservation. Economic, social and political returns from ecotourism can help to protect wildlife from poaching and wildlife habitat from clearance. Ecotourism can also modify wildlife behaviour quite significantly, however, through either disturbance or **habituation**. There are also many tourism products that are marketed as ecotourism even though they make no attempt to meet its goals, and some of these involve chained or caged wildlife and other abuses of animal welfare. Ecotourism products are structured and packaged differently in different continents and countries. Very broadly, tropical rainforest areas tend to promote **biodiversity**, with the potential to see many different species. Tours that promote individual icon species or animal families are the exception: examples include mountain **gorilla** in Uganda, **orang-utan**

P.203

in Borneo, **giant panda** in western China, quetzal in Guatemala, tiger in southern Nepal, lemur in Madagascar and possum in north Queensland, Australia.

In more open landscapes, individual icon species are a major feature in ecotourism marketing. Examples include: the so-called Big Five game (lion, **elephant**, **rhinoceros**, **buffalo**, leopard) and associated charismatic megafauna of eastern and southern Africa; wolves, bald eagle and grizzly **bear** in Alaska; polar bear in the circumpolar High Arctic; condor in the Andes and puma in Patagonia; and kangaroo and koala in Australia. Similarly, some marine ecotours promote individual species such as whale, walrus, manta ray or elephant seal, whereas others promote diverse ecosystems such as coral reefs. Many ecotourism products also feature plants, scenery, cultural attractions and adventure activities, but watchable wildlife is commonly a key selling point.

Ecotourism enterprises use both public and private land and water under various tenures, but **wildlife management** issues are commonly most contentious in public protected areas such as World Heritage Areas, Biosphere Reserves and National Parks. Many such reserves were established for recreation as well as for conservation, and many are currently experiencing an increasing influx of visitors, principally for

independent recreation but also on commercial tours. While such visitors may help in providing political support and, in some cases, funding for conservation of wildlife habitat, they may also have significant impacts on animal behaviour and population dynamics. There are even instances where tourism has threatened the survival of entire species. Equally, of course, there are instances where tourism has been instrumental in species conservation.

While the types of impacts that wildlife watchers and ecotourists can produce on birds, terrestrial vertebrates and marine mammals are broadly understood, the detailed mechanisms and quantitative effects differ greatly between species and depend heavily on activities and equipment, visitor numbers and behaviour, season and so on. Scientific research to date is quite inadequate to predict such impacts in sufficient detail for informed wildlife, habitat and visitor management.

In general, impacts that are direct, immediate and easy to observe are more heavily studied than those that are indirect, diffuse, delayed and not obvious to the naked eye. The distances to which walkers, joggers, dogs or vehicles can approach various bird species either feeding, roosting or nesting, for example, have been recorded on numerous occasions, but particularly for shorebirds in north-eastern USA (Buckley, 2004). There are far fewer cases where the energetic consequences for individual birds, the population consequences of reduced reproductive success, or the implications of less obvious impacts such as habitat modifications or the introduction of avian diseases have been assessed. There is at least one known instance, however, where a single light aircraft overflight caused the immediate death of 88% of the eggs and chicks of a colony of white pelicans in Canada.

Severe reductions in breeding success have been recorded for various northern hemisphere waterbird species subject even to very low levels of disturbance. Nesting albatross on sub-Antarctic islands exhibit symptoms of severe stress when approached by tourists, even if the birds remain on the nest. Remote telemetry has demonstrated that nesting penguins approached by tourists in the Antarctic experience increased pulse rate and temperature, physiological indicators of stress. Concerns have been expressed that they may be exposed to avian diseases through contact with tour boats. Many colony-nesting birds suffer greatly increased predation when normally vigilant nesting adults are distracted momentarily by birdwatching tourists or other humans.

A variety of similar behavioural and physiological responses to disturbance has also been found for terrestrial and marine mammals. Avoidance of tracks and trails, increased vigilance and decreased feeding, elevated pulse rates and energetic costs, introduction of diseases and interference with intra- and interspecies interactions have all been reported on occasion (Buckley, 2004). Disease introduced by tourists, for example, led to the death of six lowland gorillas in the Democratic Republic of Congo in 1988 (Buckley, 2003). A classic study by MacArthur *et al.* (1982), using remote telemetry, found that bighorn sheep in North America suffer physiological and energetic stress when approached by hikers or dogs, even if the sheep do not run away. Sperm whales subject to overflights by helicopter tours at Kaikoura, New Zealand apparently spend less time on the surface replenishing oxygen supplies. Trails made by hikers through dense forest vegetation may increase predation by feral foxes and cats on native Australian mammals.

Most of the interactions between tourists and wildlife are inadvertent. Most ecotourists prefer to watch undisturbed wildlife engaging in natural behaviours, even if in practice the tourists' ignorance of animal behaviour, or enthusiasm for a close encounter, does lead to disturbance. There are some situations, however, where interactions between tourists and wildlife are deliberate, and there is controversy as to whether or not these may constitute ecotourism. The two best-known examples are: first, deliberate habituation through feeding; and, secondly, so-called consumptive wildlife tourism such as **hunting** or **fishing**.

Most protected area management agencies specifically ban feeding of birds and animals. Reasons commonly given are that: (i) feeding leads to **abnormal** animal behaviour, which is not what visitors

should see; (ii) some animal species become aggressive when fed and may injure visitors; (iii) feeding and/or touching of wild animals may lead to the spread of diseases in local animal populations; and (iv) by boosting local populations of more aggressive species, feeding may indirectly reduce populations of more timid species, which may include rare or threatened species.

Feeding of wildlife by commercial tour operators, however, is extremely widespread. It may occur openly where it is permitted in public parks or private land, or covertly where it is not. Examples of surreptitious feeding include wallabies at the Gordon River landing in Tasmania and polar bears in Churchill on Canada's Hudson Bay. Examples where animals are fed by tourists as part of the tourist product include parrots at O'Reilly's Rainforest Guesthouse and dolphins at Tangalooma Resort, both in Queensland, Australia. However, many of the world's best-known wildlife tourism operations, both private and public, are particularly careful not to associate tourists and food. Examples include open-vehicle safaris in the private game parks of southern Africa and the management of camping permits at Denali National Park in Alaska (see Buckley, 2003 for further case studies).

P.204

Controversy over recreational hunting and fishing, especially through commercial outfitters, is even more intense than for wildlife feeding. Some people are opposed to hunting on both ethical and philosophical grounds (see: **Ethics; Morality**); others are not opposed to hunting, but do not think it should be considered as ecotourism; others again are prepared to countenance hunting as a form of ecotourism if it contributes to maintaining populations of rare or endangered species. Similar considerations apply for fishing.

The issues are commonly complex. For example, managing a hunting reserve for specific target species may reduce populations of other species that are of greater conservation significance. For example, gamekeepers in the UK may shoot golden eagles on grouse moors, whether legally or not. Conflicts may also occur between photographic and hunting operations. In areas where hunting is permitted, animals rapidly become wary, spoiling the opportunities for wildlife watching. Where animals that are habituated to wildlife tourists, however, move into areas subject to hunting, they are unafraid of humans and hence become easy prey, as in some notorious East African examples (Buckley, 2003). Advocates of hunting tourism argue that hunting can generate a great deal more revenue than photographic safaris, with far less infrastructure investment. In practice, however, it seems that, with the exception of countries with stable and effective legal and wildlife management systems, the issue of high-value hunting licences can soon become subject to abuse, with major detrimental effects on wildlife populations. This has apparently occurred, for example, in a number of African nations. Where strong legal and wildlife management frameworks do exist, however, parks agencies both public and private have been able to raise significant funds for conservation by breeding icon wildlife species and selling them either to game reserves or to hunting preserves.

In conclusion, therefore, it appears that: (i) watchable wildlife forms a major component of many ecotourism products and hence makes a very significant contribution to ecotourism revenues; (ii) while the best ecotourism products go out of their way not to influence animal behaviour, the majority do indeed produce behavioural impacts; and (iii) ecotourism may produce either positive or negative effects on wildlife conservation and animal welfare, depending on the particular circumstances.

Egg production

Worldwide there are approximately five thousand million hens that lay eggs for human consumption. In addition there are breeding birds whose eggs are fertilized and hatched to produce more layers and meat birds. One consequence of strains of hens bred specifically for egg laying is the redundancy of the male chicks. These ought to be humanely disposed of at hatching, using maceration rather than the prevalent practice of slow suffocation in carbon dioxide, which is an irritant gas (see HSA, 2001).

Original strains of hens laid eggs in batches or clutches and then became 'broody' regardless of whether the eggs were removed. Such behaviour has been bred out of modern laying hybrids. Table E.1 indicates how the productivity of hens has been increased through genetic selection and altered diets and housing. It is now approaching the biological maximum of 1 egg/day, particularly early on in the laying cycle.

As the ovum, or egg, passes down the oviduct the shell is added, the whole process taking 24-25 h. Among other factors, shell thickness depends on the quality of the diet. It used to be thought that hens drew on the reservoir of calcium in the skeleton to help calcify the eggs and that this accounted for the osteoporosis commonly seen in birds at or before the end of lay (see: **Bone strength**). However, current evidence demonstrates that a major influence is the high levels of **oestrogen** associated with egg laying that preclude the formation of bone, along with genetic and other factors (Whitehead, 2004). Most hens in intensive laying systems develop osteoporosis and have a high risk of fracturing bones. To improve economic efficiency, hens have also been selected to be smaller and thus have a lower maintenance requirement for feed. This compounds such welfare risks and reduces the longevity of the birds.

Laying hens in commercial production systems are usually culled after 50-70 weeks of age, whereas those in backyard flocks generally live for several years. A few producers, notably in the USA, use the practice of '**forced**' **moulting** where, after about 1 year of production when egg output has declined, feed and water are withheld from the hens for several days. This causes them to shed feathers (moult), which then regrow, and it also has the effect of rejuvenating the hens' egg production. There are substantial **welfare** issues associated with withholding feed - and especially water - from hens, and the practice is therefore not permitted in most countries, including the European Community.

From the mid-20th century, scientific experiments revealed that egg size and production could be manipulated by altering temperature and lighting patterns. An increased day length is now routinely used to photo-stimulate pullets to advance their sexual maturity so that they come into lay by about 18 weeks of age (see Lewis and Morris, 2006, for more details). A typical egg production curve for intensively managed layers is given in

P.205

Fig. E.8, which shows that younger birds lay more eggs per week. Egg mass output is relatively constant at a given age, so birds can produce several smaller eggs or fewer larger eggs.

Table E.1. UK housed hen egg production, 1936-2006 (eggs per bird per year) (from FAWC, 1997).

Year	Production
1936	149
1946	121
1956	170
1966	202
1976	245
1986	279
1996	310
2006	311

A number of factors influence egg size. Larger eggs tend to be laid by larger birds and egg size increases with the age of the hen, mainly due to her growth and increased bodyweight. If larger eggs are required at the point of lay, pullets are allowed to grow bigger before reaching sexual maturity. In general, warm environmental temperatures result in larger eggs as the hen has to partition less feed to maintain body temperature; however, heat-stressed birds (above about 26 °C) lay fewer, smaller eggs. The number and size of eggs can be manipulated by lighting patterns, with longer day lengths leading to increased feed intake and higher egg weight.

Eggshell colour is related to the genetics of the bird, so white-feathered hybrids (e.g. those derived from Leghorns) lay white eggs and brown-feathered birds (e.g. those derived from Rhode Island reds) brown eggs. Unusually coloured eggs, such as blue-green laid by Araucana hens, have a novelty market.

Eggshell quality has been used as a non-invasive indicator of hen welfare (Dawkins *et al.*, 2004). This and other work shows that shell thickness may decline when hens are stressed (particularly heat stress), eat insufficient feed or when dietary components are inadequate. Blood spots on the shell surface may indicate the presence of red mites. Blood streaks are indicative of vent pecking, which may be associated with either young birds laying relatively large eggs or an early onset of lay.

Electric field

The ability to detect and produce electric fields is confined to aquatic species because, unlike air, water conducts electricity, and sea water is more conductive than fresh water because it has a greater concentration of salts. The diversity of aquatic species exhibiting **electroreception** and electrogenesis is great, including the sharks and rays, teleostean fishes, lungfishes, coelacanths, salamanders, frogs and a marsupial mammal, the platypus (see Fig. E.9).

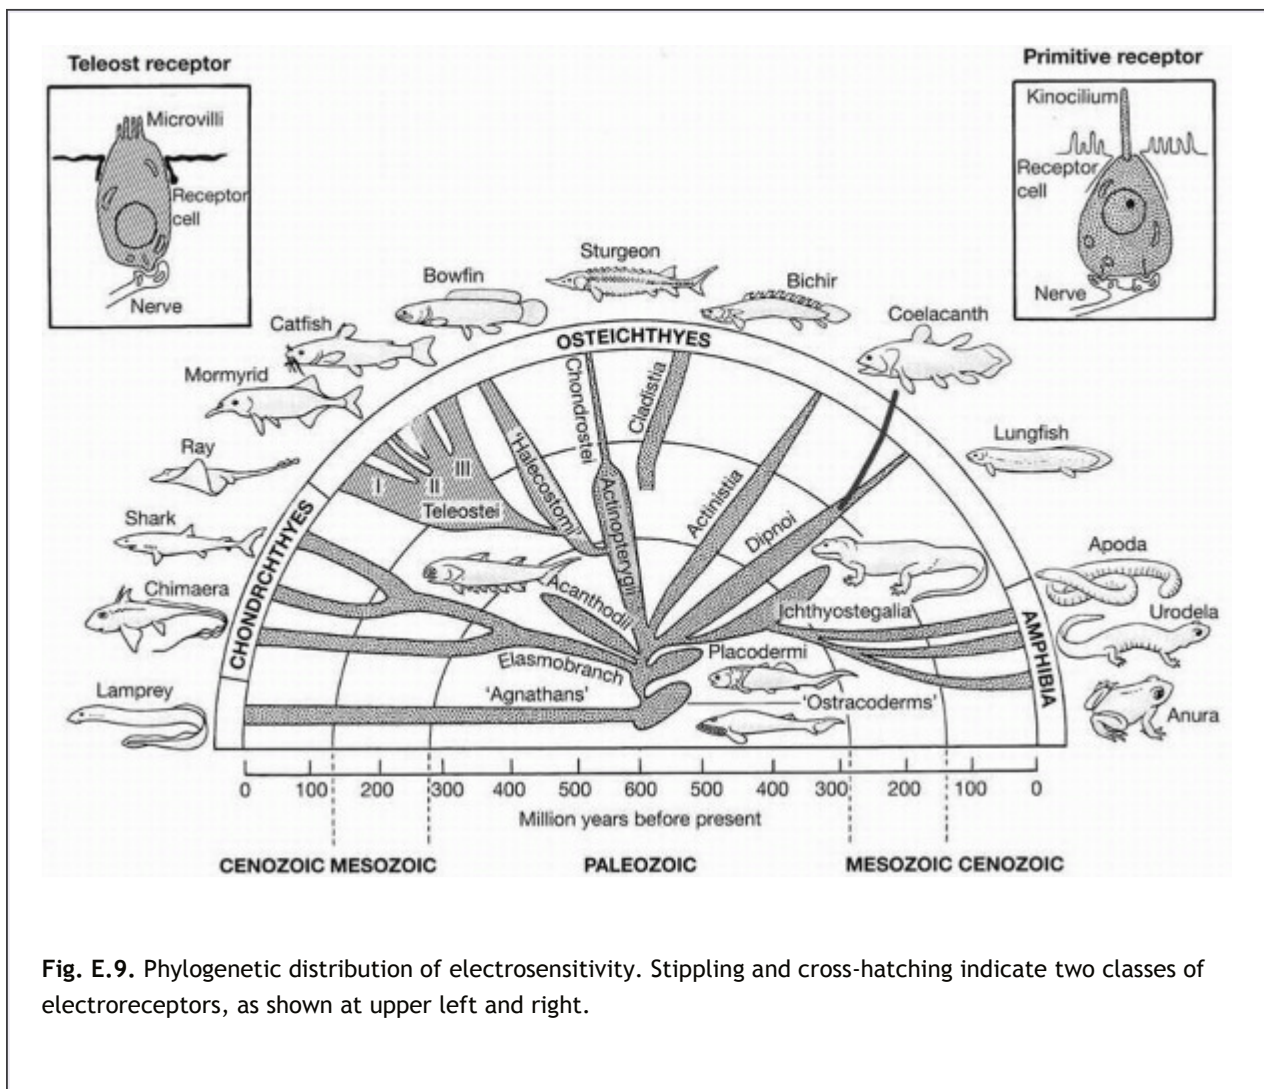

These species use the electrical sense for a variety of purposes. They detect their prey or mates by the electrical fields associated with the movement of salt water, a conductor, through gill cavity and muscle contractions, and migrate between habitats by orienting to the seafloor's local pattern of magnetization or Earth's dipolar field. They actively produce weak electric fields around themselves, and detect the proximity of objects of different conductivity by the distortion of this electric field. Finally, they immobilize their prey by generating strong electric fields. It is likely that electroreception was an early feature of vertebrate evolution, because the capability is possessed by the lamprey, the sole survivor of the large ancestral group of jawless fishes, the Agnathans, which were present 600 million years ago. However, this ability was lost once in their evolution, and was later evolved independently by the knifefishes, elephant fishes and catfishes.

Electroreception

In order to understand electroreception, it is useful to review the basics of a simple electrical circuit (see Fig. E.10). The simplest circuit consists of a battery, a resistor and a switch. The battery contains many electrons, and can be compared to

P.206

a reservoir of water; once a switch is thrown, thus closing the circuit, electrons will flow through the circuit, just as water would pass through an opening in the dam into a riverbed. However, the rate of electron flow is modulated by the resistance of the conductor, just as water flow is impeded by the width of the river bed and the number of rocks in its bed and lining its sides. Ohm's law demonstrates that the current, or electron flow through the circuit, is equal to the voltage, the density of electrons in a battery divided by the resistance of the conductor. In Fig. E.10 the battery is symbolized by vertical lines alternating in height, a resistor by the saw-shaped lines and the switch by the two small circles, one of which has a line extending from it.

The electric field shown is a dipole, consisting of a positive and a negative charge separated by a given distance, and this can be described first by equi-current lines, curved lines leading between the charges that indicate the density of electrons flowing through the medium - more flowing in a straight line between the poles, fewer at a greater distance to either side of this line. The field can be described secondly by concentric oval rings around each charge, indicating the tendency for current to flow between the two poles at greater distances. The asymmetrical concentration of electrons in the parts of any aquatic animal produces a dipolar electric field with a voltage. The magnitude of this voltage will change in time as, for example, a fish opens and shuts its mouth, drawing water through its gill cavity and passing it by its gills to respire, or contracts its muscles as it propels itself forward by beating its tail. The alternating electric fields, such as those produced as a small fish buried in the sand breathes, are detectable at night by a shark or ray with an organ sensitive to these fields.

Indeed, the sharks and rays, which are dominant predators in the marine environment, are very sensitive to electrical gradients and can perceive an equipotential gradient of as little as 1 nanovolt, or one billionth of a volt, over a distance of 1 cm. Most living animals produce electrical potentials that are much greater, often in the magnitude of thousandths of volts, over a distance of 1 cm. The cartilaginous fishes, including the sharks, rays and chimaeras, detect these fields with an organ termed the ampullae of Lorenzini (see Fig. E.11).

This consists of a minute circular opening, or pore, in the epidermis, with a tubular canal containing a non-conductive wall filled with an electrically conductive gel that leads to a lumen, or cavity, lined with voltage-sensitive cells, each having a single kinocillium projecting into the lumen. Because the canal runs for some distance beneath the epidermis, the receptor cell detects the relatively large difference in voltage, or potential electron flow, between the charged body fluids within its tissues and the electrolytic solution comprising the surrounding environment. The nerve at the base of each receptor cell fires at a constant rate, and its rate of firing is depressed in the presence of a voltage whose polarity is

P.207

positive with respect to the internal body of the shark or ray. These canals are distributed over the head on sharks, with the highest density surrounding the mouth. They are not only scattered over the heads of rays, with the highest density near the mouth, but also extend outward on the underside of their laterally enlarged pectoral fins.

denotes the voltage or potential flow and R expresses the resistance in the circuit to this flow of electrons.

Fig. E.11. Ampullae of Lorenzini. (a) Distribution of ampullae on head of spiny dogfish. Open circles represent openings to the canals, (b) Ampullary organ, consisting of surface pore and canal filled with conductive jelly leading to lumen lined by sensory cells.

The sharks and rays use this organ to detect prey or mates. A shark can locate a fish, such as a flatfish or cigar-shaped wrasse that is buried in the sand out of sight, by detecting its electromagnetic discharges. All muscle activity generates electric potentials, or voltage changes, such as short-duration pulses of electron flow caused by the release of neurotransmitters by motor neuron(s), or longer-duration pulses of electron flow associated with muscle contractions. Furthermore, the movement of water, a conductor, through the gills during respiration also induces an electron flow.

Juvenile scalloped hammerhead sharks, which live in shallow bays, swim at night 20 cm above the bottom, searching for buried prey. The laterally elongated rostrum, or hammerhead, may be an adaptation to increase the scanning surface and effectiveness of the receptor system - the pores of the ampullae of Lorenzini extend all the way to the distal ends of the laterally expanded head near the eyes. In a sense, the selective pressure on this species of shark is consistent with the impetus for an engineer to design a coin detector with a wide disc. Even the parrotfish, which escapes predation from an

olfactory-sensitive predator - the moray eel - by secreting a mucilaginous cocoon around itself to contain its excreted metabolites, is detected by the shark or ray using its electroreceptors. Rays use the electroreceptors that are distributed over their enlarged pectoral fins to detect their mates. Male

P.208

round stingrays swim into shallow sandy waters in the Gulf of California, where they locate females from a distance, change their course and move directly to them to inspect them, orienting to the equipotentials of their pulsing electrical fields (see Fig. E.12).

Finally, elasmobranches use their electrical sensitivity to navigate. The shark's body can be imaged as a conductor, and its movement through the Earth's dipolar field produces a perceptible electrical voltage. The shark can maintain a constant heading by swimming in such a way as to keep constant the voltages perceived by its ampullae of Lorenzini. Indeed, many species of sharks - such as blue, scalloped hammerhead and tiger sharks - swim in a highly directional manner for long distances at night, well below the sea surface and well above the seafloor, thus far away from fixed visual references such as the sun, moon and bottom topography that could alternatively guide their movements. There are also patterns of magnetization in the seafloor that may be perceptible to sharks. The seafloor consists of alternating bands, leading north and south, of strongly and weakly magnetized crust, and this pin-striped pattern is broken by strong dipolar fields of small islands and underwater mountains (seamounts). These two patterns are created by the cooling of magma extruded over long periods of time from the Earth's core, and the infrequent reversal of the polarity of the Earth's field gives these tiny magnetic particles a parallel or antiparallel orientation to the current polarity of the Earth's field. The night-time foraging excursions of hammerhead sharks, 20 km to and from seamount and islands, have been shown to follow magnetic ridges and valleys from the seamount associated with lava flows.

Fig. E. 12. Male stingray approaching dipolar field, showing equipotentials simulating the field of prey, to mate with a female stingray.

Electrogenesis

Fishes also produce electrical fields, which can be both weak and strong. The knifefish (Gymnotidae) and elephant fish (Mormyridae) produce weak fields around themselves, and can move around in turbid waters by avoiding rocks and other obstacles to movement by perceiving the distortion to their field caused by these objects, which differ in conductivity from fresh water (see Fig. E.13). The signals of males and females of these species differ in the waveform of their signals, and it is thought that they identify their

mates on the basis of discharge pattern. The freshwater electric eel and catfish and the marine teleost, the stargazer and marine elasmobranch - the torpedo ray - produce electrical discharges strong enough to stun their prey.

These electrical discharges are produced by modified muscles, termed electrocytes, that have lost the ability to contract, but have gained the ability to generate ionic current flow. Each electrocyte resembles a small comb standing on its side, with a smooth side, which is innervated, opposite a rough or multi-fingered side. The inside of the membrane on the smooth side of the electrocyte is negatively charged with respect to the surrounding extracellular fluids, due to the exclusion of sodium ions by the cell membrane pump. When the cell is stimulated by the nerve discharge, the sodium ions pass rapidly through the smooth side to produce a positive voltage, while the ions stay in place on the rough surface, which is not innervated. This results in a voltage potential across the entire cell, including the smooth and rough surfaces, of 151 mV. The electrocytes are arranged in stacks, and a single stack may contain as many as 10,000 layers. Their voltages sum like those of multiple batteries arranged in series, each with its positive lead next to the negative lead of the adjacent battery, to generate potentials as high as 600 V, as recorded from the electric eel in the Amazon River of South America.

The knifefish of South America and elephant fish of Africa, which produce weak electric fields, live in freshwater rivers and lakes. They produce discharges that are either continuous waveforms or series of pulses, yet they discharge often in contrast to those fishes that produce strong voltages. This is because they are nocturnal and live in highly turbid waters, where vision is of limited use, and they use these fields to navigate in their local environment. These fields can extend outward as far as 50 cm from the body, and the field is distorted by objects that are either less or more conductive than fresh water. Rocks are highly conductive, while other fishes, invertebrates and even plants are more conductive. These distortions of the field produce a change in the distribution of the equipotential lines across the fish's body. Because of the energetic cost of producing this field, the majority of the weakly electric fishes produce pulsed electrical fields, varying in frequency between 50 and 300 cycles/s.

The skin of these teleosts has a specialized electric receptor, the tuberous organ, which probably evolved much later than the ampullae of Lorenzini at the beginning of the Mesozoic age, 280 million YBP. These receptors are derived from the

P.209

neuromast receptors of the lateral line, and differ from the ampullae both anatomically - in that they have many small microvilli at their surface - and physiologically - in that they respond to an external voltage that is positive with respect to that of the cell, by increasing their rate of discharge. During each organ discharge, an inhibitory command is issued to the electroreceptors so that they are insensitive to their own discharge, yet between the discharges they turn on and report the distortion of the electrical field by the presence of a foreign object. The nature of their discharges varies with their sociability and habitat. For instance, social species that live in shallow and narrow streams have pulses of short duration in order to avoid interference with the discharges of their neighbours. In contrast, solitary territorial species have longer electric discharges. The waveforms of males and females differ, and these are used during courtship by sexually active males to identify receptive females. Yet this social advertisement has a cost - a predator such as the electric eel can use its electrosensitive organs to locate these fish by orienting to their **courtship behaviour** signals.

The primary function for the generation of weakly electric fields is navigation, and hence they are relatively continuous. Therefore, these species are largely confined to rivers and lakes with fresh water of low conductivity. It would be difficult to maintain this ability in the marine environment - the energetic cost of maintaining fields at any distance from themselves in the highly conductive marine waters would be prohibitive. The fish that produce strong fields need to do so infrequently to stun their prey. These fish exist in fresh water, such as the electric catfish in the Nile River and the electric eel in the Amazon River. However, there are also species in the marine environment with the same capability. These species must be close to their prey to stun them, due to the high conductivity of salt water. For that reason, the stargazer remains motionless on the bottom, looking upward for above-swimming prey, and produces a voltage sufficient to stun it as it passes closely over. The torpedo ray drifts slowly through the water at night and alters its path ever so slightly so that it can move close to small fish, and then discharges its electrical organs while moving its pectoral disc into a concave shape around the prey, so that its body is as close as possible to the prey before discharging its electrocytes.

In conclusion, the evolution of the electrical sense has played a major role in adapting species to aquatic and marine environments. It has enabled these species to find their way in an environment where vision is of less value than in the terrestrial environment. It is also effectively used to detect prey and find mates and, hence, the sense has evolved at least twice during the evolutionary history of animals on our planet.

P.210

Electric/electronic training aid

Numerous electrically activated training devices are available for use on animals worldwide. Their use is a contentious and emotional issue and is often justified by the suggestion that they are a last resort and hence an alternative to euthanasia. They are often seen (and marketed) as a quick-fix answer to problems that may have been ongoing for years. The use of these training aids is legal in some countries and illegal in others.

Electric training aids have been used to confine animals, to deter unwanted behaviours such as barking and to attempt to train new or desirable behaviours. They are available in several versions: (i) operator controlled (i.e. the operator decides when to trigger the device); (ii) environmentally controlled (e.g. where the location/distance of the device relative to the animal within the environment triggers the device); and (iii) animal controlled (i.e. the animal's behaviour triggers the response, e.g. volume of bark).

Devices can include collars (used on dogs and horses) or electric mats (cats) that may be paired with a noise (e.g. hissing from compressed air), a smell (e.g. citronella collars) or a discharge of electricity between two metal probes in contact with the skin of the neck (e.g. the electronic stimulus/shock collar). They operate on the basis of positive punishment, whereby the devices are activated to produce an aversive stimulus at the time the animal exhibits the unwanted behaviour.

For these electric training aids to be effective on their own they must, by definition, provide an aversive stimulus and so have the potential to inflict pain and suffering on the animal. The correct use of punishment is critical if it is to be effective. That said, training aids that inflict punishment may actually impede learning, especially in anxious animals. In some cases, they are used at a low level to interrupt behaviour and facilitate positive reinforcement of the correct behaviour.

Concerns about the possible consequences of the use of some of these devices for animal welfare relate to the extent to which they inflict pain. The type of pain may be acute at the time the stimulus is applied

or may be chronic, affecting behaviour subsequently (as shown by several studies). The extent to which individual animals suffer pain varies considerably both between animals and within the same animal under different environmental circumstances.

Research has shown that, in some cases, the use of electronic devices may cause **distress** and potentially harmful responses, both physical (e.g. skin damage) as well as psychological (e.g. increased **anxiety** or **fear**) in some animals. They may also exacerbate the unwanted responses. For example, they may increase reactivity in an aroused or aggressive animal. Additionally, since a dog that is adversely affected by the collar cannot remove it, distress and possibly even **learned helplessness** may occur. None the less, they can be effective, leading to a debate concerning the **ethics** of their use.

Some of the behaviours that electric training aids are employed to change are normal behaviours. Attempting to stop normal behaviours may well be detrimental to the animal's welfare, if the behaviours are highly motivated. An alternative approach to stopping the undesirable behaviour is to consider its motivation and consider allowing another acceptable outlet for the behaviour, or to eliminate the stimulus for the behaviour.

For example, when attempting to modify a dog's barking or contain a dog in a yard it is important to first establish the reasons for the barking or attempts to escape. Treating the problem symptomatically, e.g. only by stopping the barking or confining the dog, may be ineffective as well as harmful. Failure to address the underlying causes of the behaviour often causes the problem to continue, and may also lead to further anxiety or possible pain.

Operator-controlled collars are difficult to use consistently within the guiding principles of learning theory criteria. For example, to be effective, punishment needs to be administered at the time of the behaviour. Even experienced trainers find that this is not always possible. The punishment also needs to be applied every time the behaviour occurs but, unless the operator is present 24 hours a day, 7 days a week, this criterion cannot be satisfied.

Electronic boundary collars are often used to confine dogs and other animals to specific areas of a property, for example when traditional fencing is impractical or prohibitively expensive. They may also be used to restrict access to certain areas (e.g. flower beds). If they succeed in keeping the dog inside a defined area, hence preventing roaming and thus reducing the chances of a road traffic accident, then they may have positive welfare implications for the dog, the owner and the community. However, if their use results in the dog being attacked by another dog entering its property, it would appear that the welfare of the resident dog can also be compromised.

The use of electric training aids is problematic. Even if these devices are used only by people with specialized training, under very controlled, exceptional or specific circumstances, they can still be misused and abused, and can cause pain and physical, as well as psychological, damage to the animal. With increasing knowledge about behaviour modification it is clear that alternative methods are usually available.

The fundamental problem with such devices is that they attempt to control signs (for example, barking or escaping) without addressing the possible underlying causes for the behaviour. They may exacerbate the problem and may also have significant welfare implications for some animals.

As veterinary behaviour therapy has developed since the 1990s, the use of 'punishment' in behaviour modification has fallen out of favour and has been largely displaced by the use of reinforcement (any approach that encourages the animal to exhibit the desired behaviour).

Electrocardiogram

The transmission of electrical activity throughout the heart gives rise to an electrical field that can be continuously

P.211

detected through appropriately placed sensory electrodes on the body surface. The electrodes register voltage differences produced by the heart that can be plotted on to paper, or displayed online, to form an electrocardiogram (ECG). Generally, in humans 12 to 15 leads are attached to electrodes and placed in a bipolar arrangement on the body. In animals, however, fewer leads (e.g. three to five) or implantable biotelemetry transmitters may be used for easier and longer-term bipolar or unipolar ambulatory monitoring.

Fig. E.14. Electrocardiogram (ECG) showing the location of the P, S and T waves and the QRS complex.

A normal ECG has three principal components that represent different facets of cardiac activity (see Fig. E.14): the P wave, the QRS complex and the T wave. The small, rounded P wave represents atrial depolarization, and results in the contraction of the atria. Following on from this is the PR (PQ) segment, which represents the movement of depolarization through the atrioventricular node. The magnitude of this is too weak to be detected, so it is characterized by a 0 mV segment. Next comes the QRS complex, which corresponds to the movement of the depolarization from the atrioventricular node to the interventricular septum. This stage is also referred to as ventricular depolarization. Once again, voltage returns to 0 mV before ventricular repolarization occurs, forming the T wave.

Repolarization of the atria is not evident on an ECG, as it occurs during ventricular depolarization. In medical environments the ECG is frequently used for the observance of cardiac defects, arrhythmias, heart disease and so on. In animal behaviour research, the ECG has been successfully used as a tool to evaluate and compare different welfare states, including response to stressful events and painful procedures.

(RM-F)

Electroception/electroreception

Electroception is the ability to perceive electric impulses. Many primitive fish (e.g. sharks) can detect electric fields generated by other animals and thus use passive electroception. Among mammals, only the monotremes (e.g. platypus) have provided convincing evidence of being electroreceptive. Other animals, such as electric fish, use active electroception, as they can generate electric fields: they are electrogenic. Electroception can be used for electrolocation (i.e. location of objects) in the context of prey location or navigation. It can also be used for electrocommunication among animals that can modulate the electrical waveform they produce.

Electroejaculation

Electroejaculation involves the use of a rectal probe to electrically stimulate erection and ejaculation in male animals; it is a long-established technique, with the first report of its use being in 1936. It is routinely used for captive species where semen collection is required for assisted-breeding programmes. For domestic species where regular semen collections are required, males are generally trained to ejaculate into an artificial vagina or in response to manual manipulation, but electroejaculation is still used for untrained or recalcitrant males where semen samples are required for breeding soundness examinations.

Use of electroejaculation has a number of advantages: (i) it is independent of the male libido status, and so does not require the presence of teaser oestrous females or dummy mounts; (ii) it does not require training, which can be a time-consuming process that cannot be justified for a one-off collection; (iii) it can be used on anaesthetized or sedated animals where there are serious safety or handling considerations; and (iv) it has a high success rate in inducing ejaculation.

Emission, transfer of semen from storage in the *ampullae* and *vasa deferentia* into the pelvic urethra, erection and ejaculation are all achieved by a combination of smooth muscle contraction and vascular mechanisms initiated by the **parasympathetic** and **sympathetic nervous systems**. Stimulation is via a cylindrical probe with a series of longitudinal ventral electrodes; older-type probes had ring electrodes around the probe, which resulted in additional dorsal stimulation of motor nerves, causing muscular contractions in the back and hind limbs that could be sufficiently severe to cause soreness and bruising. Ventrally oriented electrodes focus the electrical stimulation in the required area, reducing unwanted motor stimulation.

The majority of modern systems use a sine wave pulse with a frequency of 20-30 cycles/s and a variable output up to 16 V (< 900 mA) that is applied intermittently in series stimulations lasting a few seconds, with rest periods in between; voltage may be increased with each successive stimulation until ejaculation is achieved. More advanced systems allow a set stimulation sequence to be pre-programmed into the probe. In large domestic species stimulation may be preceded by transrectal massage of the accessory glands to sexually stimulate the animal; in some cases massage alone may induce ejaculation, but success rates are much more variable than those achieved using electrical stimulation.

The major problems with the use of electroejaculation are the **welfare** considerations consequent on the degree of **pain** or discomfort associated with the procedure. The extent to which the procedure is painful is not clear; in human cases where electroejaculation has been used to overcome ejaculatory failure, the procedure is known to be painful and only performed under anaesthetic. However, with domestic livestock, general **anaesthesia** carries its own risks and a number of studies have investigated the acceptability of electroejaculation on welfare grounds. Within the UK, welfare **codes of**

P.212

practice stipulate that the process should only be performed by a veterinarian, and electroejaculation without anaesthesia is discouraged. Some European countries have gone further, banning the process completely and even banning the import of semen collected without anaesthesia. Electroejaculation has been shown to be an aversive procedure, but only to an extent comparable to other routine stock procedures requiring handling and a degree of **restraint**, such as shearing of sheep.

Levels of pain associated with the procedure may be mitigated by good operator procedures and the use of up-to-date probe designs, with protocols involving minimal stimulation. While aspects of electroejaculation usage may be controversial, it remains a routine and widely used procedure in domestic livestock production, and has a growing role in assisted reproduction protocols for endangered and exotic species. However, electroejaculated semen tends to be of lower quality than a natural ejaculate.

(MRC)

Electroencephalogram

An electroencephalogram (EEG) is a non-invasive and painless test that detects electrical impulses (activity) in the brain. It consists of different kinds of waves traced on graph paper, representing brain activities.

When a group of **neuron(e)s** is excited simultaneously (synchronously), the action potentials of each neuron sum to generate one large surface signal. The signal can be recorded by placing small metal electrodes on the external surface of the head, and is shown as EEG waves on either graph paper or a computer screen. Based on frequency range, the various brain waves have been categorized and named:

- alpha (α) waves - relatively slow, with a frequency of 8-12 Hz;
- beta (β) waves - with higher frequency (13-30 Hz) and lower amplitude;

- theta (θ) waves - with a frequency of 4-7 Hz;
- gamma (γ) waves - with a frequency > 30 Hz;
- delta (δ) waves - slow, with a frequency < 4 Hz but large in amplitude.

The EEG waves vary dramatically and often correlate with particular states of behaviour, such as level of attentiveness, sleeping and waking, and pathological changes, such as seizures or coma. In general, high-frequency, low-amplitude rhythms are associated with alertness and waking or the dreaming stage of sleep; low-frequency, high-amplitude rhythms are associated with non-dreaming sleep states and with the pathological state of coma. When the EEG changes from α to β waves, from synchronization to desynchronization (activation) of the EEG, an arousal is produced.

In particular, through examining the characteristics of wave patterns, the EEG provides us with a convenient window on the structure and functional states of the brain in both healthy individuals and those with psychiatric illness, such as **anxiety**, mood disorders and post-traumatic stress disorder. When an animal is sick, hurt or stressed, electrical messages to and from the brain can be changed or blocked, resulting in changes in EEG waves. The EEG test can pinpoint the location of these neural changes, and has been used to help in the diagnosis and find the causes of certain neurological and psychiatric conditions, especially seizure disorders, strokes, brain tumours, head trauma, metabolic dysfunction, vascular disease and infections of the nervous system, as well as certain mental responses, such as those associated with **social stress**, **emotion** and **cognition**, all of which affect brain function. In addition, a high-resolution EEG structure analysis has been used to examine stress-induced states and their correlations with the resonance activation of the brain.

However, EEG has certain limitations in practice. One limitation is that most rhythms have no direct linkage with the brain function. Instead, they may be just by-products of the interconnections of various forms of excitatory feedback of the brain circuits, regardless of stimulators. For example, a similar EEG could be recorded from the instability or oscillation of the brain actions induced by either an audio amplifier or a human stadium ('Mexican') wave. In addition, EEG is difficult to interpret and subject to some errors. Recently developed, quantitative EEG gives a much more accurate and representative view of the location within the brain of the alterations of EEG activity, through the qualitative assessment or overall appearance of the rhythms and amplitudes and their changes.

(H-WC)

Elephant

Elephants are the largest living land mammals, with adult males standing nearly 4 m tall and weighing up to 7000 kg. Besides their immense size, elephants are known for their dexterous trunk, large tusks and matriarchal family structure. There are two genera of living elephants (Proboscidea: Elephantidae) - the Asian elephant (*Elephas*) and the African elephant (*Loxodonta*). The former may have three subspecies, with Indian (*E. maximus indicus*), Sri Lankan (*E. m. maximus*) and Sumatran (*E. m. sumatranus*) forms, although some recent evidence suggests that the Indian and Sri Lankan forms are not distinct, but a Borneo subspecies may be reinstated.

Currently, the African Elephant Specialist Group (AfESG) of the International Union for the Conservation of Nature (IUCN) recognizes only a single African species with two

subspecies, the savannah elephant (*Loxodonta africana africana*) and the forest elephant (*L. a. cyclotis*). African elephants are tallest at the shoulder, with large, Africa-shaped ears, two 'fingers' on their trunk tip and lozenge-shaped loops on their teeth. The forest subspecies is considerably smaller than the

savannah elephant. Asian elephants are tallest at the head, with India-shaped ears, a single trunk tip 'finger' and compressed loops on the teeth. Female Asian elephants have reduced or no tusks.

Elephants are endangered in the wild, with population estimates of approximately 660,000 for all African elephants and estimates ranging from 30,000 to 50,000 for Asian elephants. While fewer than 1000 African elephants are maintained in captivity, primarily outside of range states, there may be as many as 15,000 Asian elephants in captivity, mostly in range states. Humans have a long history of using Asian elephants for labour, especially in lumbering. Habitat loss and degradation are a continual problem for the maintenance of elephant populations, with direct loss through hunting for ivory an important contributing factor. Human-elephant conflict involves competition for space and food, resulting in crop loss and sometimes death of humans as well as harassment, injury or death of elephants. Management of elephant

P.213

populations, all of which are confined to some degree, is controversial yet critical to the long-term coexistence of humans and elephants.

Elephant society centres on calves that are cared for by a matrilineal assemblage of related females and their older offspring. The youngest elephants are most susceptible to predation and, when alarmed, elephants perform numerous alert behaviours, including formation of a phalanx around the calves. The eldest female is generally the matriarch, with a linear dominance **hierarchy** among females established on the bases of age and size. Group size is larger with older matriarchs, who are a valuable source of information to facilitate survival. The family is the core social unit, although forest elephants may reside more as mother-offspring groupings. Related families may travel together in kin groups, and these may unite into larger social groups, especially in savannah African elephants. Although likely to be a rare occurrence, unrelated females may join a group or coalesce into a functional herd, especially after alterations in normal herd composition such as through heavy hunting.

Captive elephants outside of range states usually reside in unrelated groups, often with no or few calves. In the wild, males remain in the natal group until after 10 years of age, although they commonly range away from the herd core more than same-aged females before this age. Males may travel in bachelor groups, especially when younger, or more commonly alone as adults. Males reach adult female size by their late teenage years but, in general, they are not viable mates until at least their mid- to late 20s.

Elephants breed year round, although seasonality is evident in areas of pronounced wet and dry seasons. The oestrous cycle lasts 14-16 weeks, with 3-5 days of receptivity. Females usually mate for the first time between 10 and 16 years of age. Unique to elephants, there are two **luteinizing hormone** (LH) peaks, with an anovulatory surge 3 weeks before the ovulatory surge. Female Asian elephants release an oestrous **pheromone**, (Z)-7-dodecen-1-yl acetate, in their **urine** that increases in concentration from the first to the second LH surge. Female African elephants also appear to release a chemical signal by which males can detect forthcoming ovulation. Adult males enter a rut-like condition known as must (musth), during which they demonstrate increased **testosterone** levels, chemical signal release through the temporal glands and urine, **aggression**, competitive ability, and association with females leading to offspring production. Auditory and postural cues also signal **oestrus** and must. The gestation period is 22 months, with a single offspring - or rarely twins - undergoing an extended developmental period following **parturition**.

Elephants occupy a wide variety of habitats, from forests to deserts. Asian elephants tend to graze more, while African elephants tend to favour browsing, but all elephants have an expansive herbivorous diet in which they use their dexterous trunk, resilient tongue, strong tusks and huge body to feed on small plants to large trees. The sexual dimorphism of elephants is reflected in slightly different foraging patterns, with males opting more for quantity while females select for quality of vegetation.

Elephants also show dimorphism in their communication patterns. Females have a larger repertoire of **vocalizations** and may use infrasonic vocalizations not only for distant communication but also for

regular, nearby interchanges. Some elephants have been recorded mimicking trucks, other elephants and even a human handler. Both sexes use chemical signals extensively, with females showing greater interest in body regions that may release signals, such as the genitals, than in excretory products, whereas males regularly inspect urine and faeces. Auditory and olfactory stimuli may be useful enrichment tools in captivity but, without additional **reinforcement** or variation in presentation, elephants are likely to habituate quickly.

Elephants live in complex social groups and can use their trunks to fashion tools that can be used to remove ectoparasites or to obtain food. Elephants can be trained for a variety of tasks, which has made them valuable in labour and entertainment. In the wild, they demonstrate caring for injured or recently deceased relatives. Recent increases in elephant aggression towards humans and their machinations have raised the question of chronic stress in elephants driving them to unusually erratic behaviour. Further research on elephant behaviour and conservation is needed to maintain healthy elephant populations in a sea of humanity.

Elevated plus-maze

The elevated plus-maze is an apparatus used in behavioural tests of **fear** or **anxiety** in **rodents**. It is shaped like a plus sign with four arms, two of which have vertical sides and an end wall, whereas the other two arms have no sides or wall. It is usually raised approximately 30 cm from the floor. Rodents exhibit **thigmotaxis**, i.e. they prefer to stay close to vertical surfaces, so when they are placed in the elevated plus-maze, less fearful animals make more frequent and longer visits to the open arms. This test is used widely in the development of anxiolytic (fear-reducing) drugs for humans.

(CS)

Elimination behaviour

Elimination behaviour includes defecation and urination. Young mammals change their diet as they undergo the transition from neonate to juvenile and there is a consequent shift in their water balance and digestive function, as reflected by a decreased frequency of urination and an increased frequency of defecation. It is worth noting that **urine marking** and **scent marking** are not considered forms of functional elimination.

As adults, some species (such as horses and dogs) are prompted to defecate by the sight of faeces or the action of a conspecific defecating. Drinking and eating are also thought to stimulate defecation, possibly via a gastro-colic reflex. This has important implications for those seeking to house-train domestic animals, since it is necessary to take the animal to the appropriate area for elimination immediately after feeding it. Other critical precursors to elimination in young animals include waking and **play**.

P.214

While ruminants often eliminate indiscriminately, other species (e.g. horses) show considerable care in the selection of defecation sites, since they return repeatedly to areas not used for grazing. Preferred substrates for defecation can have a critical influence on the success of house-training strategies in **pet** species. Cats' preference for deep, sandy litter is a good example, since the absence of key properties in the litter offered can precipitate **house soiling**.

Although coprophobia is a common feature of domestic animal behaviour, faecal material is very useful in communication between **conspecifics**. For example, stallions indicate their presence by piling their faeces, a strategy that avoids confrontation between stallions. Middening by cats and defecation against trees by dogs are similar examples of faecal marking.

Arousal in the form of both **fear** and excitement can also stimulate animals to defecate. Indeed, increased frequency of both defecation and urination has been used as an indicator of social distress in isolated horses and laboratory **rodents**. As with defecation, some species - and most often the males - use **urine** as a marker. Stallions generally visit latrine areas to urinate, but also use urine to mask the **odours** of conspecifics.

Urination in females often becomes elaborate when they are in **oestrus**, as it seems to provide a visual stimulus to mating partners and also provides chemical signals. An example is the clitoral winking that occurs in mares after urination, but which is far more frequent when they are in oestrus. In oestrus, mares pass less urine at each urination. Urination often occurs as a spontaneous solicitation and in response to a **teaser**.

The number of urinations per day reflects the balance between water intake and water loss, e.g. through sweating, and so is negatively correlated with exercise. Although it may reflect the presence of cystitis or urinary calculi, polyuria (excessive urination) is usually a consequence of **polydipsia** (excessive drinking) that can be somatic or, far more uncommonly, **psychogenic** in origin. Accurate determination of water intake is an important step in defining the extent of the problem, while direct observation of the animal's drinking and eating behaviour can help to identify contributing behavioural anomalies, such as excessive use of salt licks.

(PDM)

Emancipation

Emancipation refers to the process by which behaviour becomes independent from the originally eliciting stimuli and motivational (proximate) states. Emancipation is used for analogous processes on evolutionary and ontogenetic timescales (see: **Evolution**; **Ontogeny**).

In evolutionary terms, emancipation relates to the evolution of signals and displays, and goes together with **ritualization**. Many signals and displays are derived activities, originating from behavioural responses to motivational conflict (e.g. **displacement behaviour**, intention movements). Activities derived from motivational conflict have frequently evolved in the context of agonistic encounters (threat, **appeasement**) and **courtship behaviour**. Through emancipation, the behaviour became increasingly independent of motivational conflict. For example, ritualized displacement activities are among the most frequent courtship displays in many birds.

Ontogenetic emancipation refers to an analogous process in behaviour development, for example in stereotypic behaviour (see: **Stereotypies**). Stereotypies also originate mainly from behavioural responses to conflict and thwarting (e.g. adjunctive behaviour, **appetitive behaviour**, displacement behaviour, intention movements and **redirected behaviour**). In the course of development, these source behaviours become increasingly independent from the original situation of conflict or thwarting, and elicited by a wider range of stimuli and motivational states. Eventually, stereotypies may persist even under conditions

where they would not normally develop. For example, environmental **enrichment** introduced after 3 months fully abolished stereotypies in bank voles, while the behaviours were only partially abolished if enrichment was introduced after 6 months and after 9 months it had no effect on stereotypic behaviour.

This change in functional context goes together with changes in form and performance of the stereotypy that are analogous to ritualization. In the evolution of signals and displays, ritualization renders the behaviour less ambiguous and more conspicuous through exaggeration (behavioural and morphological), rhythmic repetition and rigidity in form. Similarly, stereotypy performance increases in frequency and duration, while becoming increasingly repetitive and invariant. Two different ideas were proposed to explain emancipation of stereotypies. First, stereotypies might be learned responses to cope with adversity. Emancipation may thus reflect generalization of the **coping** response from the original situation of conflict or thwarting to other adverse situations. Second, stereotypies might reflect acquired brain dysfunction. According to this view, emancipation might either reflect progressive sensitization of the repeatedly activated neural pathways mediating the behaviour or, alternatively, progressive disruption of inhibitory mechanisms of behavioural control.

(HW)

Embryo

From the stage that an egg is fertilized, the resulting zygote divides to become an embryo, i.e. from the two-cell stage onwards.

(DBM)

See also: **Fetus (foetus)**

Embryo transfer

Embryo transfer is the artificial transference of an embryo from one female reproductive tract to another, normally carried out in the first few days after fertilization, with the aim of it developing into a newborn animal in a surrogate mother that is not its dam. The embryo may be genetically manipulated *in vitro* before being transferred (see: **Transgenics**). It is important that there is synchrony between the age of the embryo and the recipient uterus or oviduct in terms of the number of days following ovulation, otherwise the embryo will not implant.

Emotion

The terms 'emotion' and 'affect' are often used synonymously, and there is no universally accepted definition of either term. Affect may be considered as referring to the range of emotional processes that can bias **cognition** and the expression of

P.215

behaviour, and includes emotional reactions, mood and aspects of **temperament** and their conscious representations as **feelings**. Emotion is not a unitary entity, but it arises, in one form or another, as a

result of appraisal of the circumstances by the individual, and highlights the personal significance of stimuli. It may or may not involve self-perception. Emotional influences can lead to differences in response to stimuli that may arise as a result of generalization from previous experiences. The concept of emotion is therefore inextricably linked to the processes of **reinforcement** and **motivation**.

The subjective nature of the phenomenon has posed difficulties for its scientific investigation, although it has historically been of great interest, with four elements of emotional processes being emphasized in its investigation: its role in appraisal; the effects of emotional arousal; the function of its expression; and its role in preparing the animal for future action. **Charles Darwin (1872)** famously addressed the subject in his text *The Expression of Emotions in Man and Animals*, in which he documented the consistency of expression of analogous emotional states in different races, and also proposed general principles associated with their expression across the animal kingdom, most notably the 'principle of antithesis'. This states that signals with opposite meanings are often conveyed using opposite expressions. Thus a frown is in many ways the physical opposite of a smile, and confidence is often expressed through extraversion and expansion, while **fear** is conveyed by introversion and withdrawal.

Darwin concluded that many of these expressions have an innate basis, although they may be influenced by learning and culture. He suggested that certain stimuli give rise to a central emotional response that, as a result of selection, has been directed towards evoking specific bodily expressions that communicate this. However, **William James (James, 1884)** - another early pioneer in the field - took the opposite and, perhaps what might initially appear counterintuitive, view, by suggesting that the bodily changes arose first and it was awareness of these that gave rise to the feelings; for example, by feeling our heart rate increase and running away in response to the sight of a bear, we become scared. In so doing he emphasized the role of the emotional response in arousal, appraisal and preparation for action. He argued that, if it were otherwise, then there would be no function for the emotion, i.e. we could run away from a bear without having to feel scared of it.

However, a fundamental problem with the model proposed by James related to which emotion we should feel in any given situation, as it was argued that the autonomic response is similar even for opposite feelings, e.g. happiness and fear both evoke a strong response from the **sympathetic nervous system** (see: **General adaptation syndrome**). **Walter Cannon (Cannon, 1927)** therefore proposed that the emotional and physiological responses arose independently and simultaneously following appraisal of the situation, the latter preparing the body for action and the former giving it a qualitative dimension. These approaches have dominated our thinking about emotion, and debate continues as to what is an emotion. Each of the four elements of the emotional process mentioned above is briefly considered below.

Defining the features of emotional processes

If emotional processing involves personal appraisal, it is important to determine the criteria that may be used in this process. It has been proposed that there are two stages to this process. Primary appraisal involves evaluating the threat or benefit posed by the current situation to the individual. Secondary appraisal is then used to evaluate the options available to manage the situation and whether these are likely to be successful. Both may influence the final assessment. Thus the presence of an aversive stimulus (primary appraisal) that the animal obviously cannot tolerate, escape from or adequately control (secondary appraisal) may lead to sadness, whereas the same stimulus given in a context that the animal does feel it can cope with may give rise to hope and a very different behavioural strategy. Both types of appraisal may be affected by previous experience. From a welfare perspective it would be useful to determine upon which dimensions appraisal is made, as these will largely determine the individual's well-being at any given time. Secondary appraisal may be particularly important if the importance of allostasis as a mechanism for safeguarding welfare is recognized.

Emotional processes are undoubtedly associated with changes in arousal, with the balance between the **parasympathetic** and **sympathetic nervous systems** being an integral part of this change. However, it is now recognized that it is possible to distinguish the physiological response associated with some emotional states (McNaughton, 1989). No single measure may distinguish one emotion from another but, by measuring **heart rate** and diastolic and systolic **blood pressure**, it is possible to distinguish between fear, anger, sadness, mirth and sexual arousal in humans (see Table E.2), and this presumably reflects different neurochemical cascades within the body as well.

Such physiological distinction means that it is not necessary for emotions to be conscious in order to be qualitatively different. Thus, it is suggested that the term 'feeling' be used to describe the conscious representation of an emotional process, in order to avoid confusion and distraction related to the issue of **consciousness** when trying to scientifically evaluate the subject of emotions in animals. A change in arousal may not only be a consequence of emotional processing, but it may also influence processing. For example, if animals are administered the **beta-blocker** propranolol, which inhibits the effect of the sympathetic nervous system, aversion learning may be disrupted. These drugs are also used clinically in man and other animals to assist in the management of fears and phobias, since by reducing arousal they potentially reduce the magnitude of the perceived threat. Thus arousal does not seem to determine the emotion, but it may influence it.

Table E.2. Relative change in three cardiovascular parameters associated with different emotional states, showing how they may be distinguished physiologically (original data from various sources and summarized in McNaughton, 1989).

Emotional state	Heart rate	Systolic blood pressure	Diastolic blood pressure
Fear	R	R	R
Anger	RC	R	RC
Sadness	L	R	R
Mirth	R	U	U
Sexual arousal	U	R	R

R, raised; RC, raised considerably; L, lowered; U, unchanged.

P.216

The expression of emotion may play a similar role to arousal in providing **feedback** to the individual that influences the emotional response (biofeedback). In humans it has been found that by subconsciously manipulating the facial expressions of people (by asking them to hold a pen horizontally using either just their lips at the front of their mouth or across their back teeth, to create more of a frown and smile,

respectively), their judgement of ambiguous stimuli may be biased in line with the facial expression associated with a given emotion. This phenomenon is also exploited clinically within the field of animal behaviour modification, by encouraging animals to adopt relaxed postures during **systematic desensitization** to minimize arousal to the problematic stimulus. The expression of emotion also has communicative value to both **conspecifics** and heterospecifics; for example, dogs appear to process differently novel faces portraying different emotional expressions (**see: Facial recognition**) and respond differentially to commands with different emotional quality spoken for the first time by a trainer. However, the role of learning in these phenomena remains uncertain.

The influence of emotions on preparing the body for action is diverse. The emotional response may not only bias the type of action taken, and so certain emotional states - such as sexual arousal, intricately linked to the specific motivational states, and the tendency to engage in **reproductive behaviour (see: Motivation)** - but it may also prepare the body for learning about certain types of association, e.g. conditioned avoidance, which affect its future state of preparation. Conditioned emotional responses may play an important role in increasing behavioural flexibility and optimizing **fitness**, through the preparation of the animal for future likely experiences. The importance of emotion on learning varies with the task involved, and emotional influences may be minimal in certain forms of procedural learning, such as that involved in the acquisition of specific motor skills.

Ultimately, emotions help animals to cope with and minimize the impact of **stress** by preparing for it in both the short and longer term. Given that different types of **stressor** have different relevance in different species, it is likely that they will have different emotional processes and potentially associated experiences. For example, socially related emotional processes such as embarrassment or jealousy would not be relevant to an animal with little social complexity in its interactions, such as a cat. It might be that there is a relatively small number of primary emotional processes associated with key biological functions, e.g. acquisition of key reinforcers and avoidance of specific dangers, with secondary emotional processes arising as a result of the interaction of these or more specific contextual circumstances; alternatively, a negative emotion associated with danger may give rise to fear, but negative emotion associated with the absence of others may give rise to loneliness. However, a consensus on the primary emotional reactions of even man has yet to be reached, and so agreement in non-human animals is an even more distant prospect. None the less, a neuroscientific approach in which specific circuits are identified may be more fruitful (Panksepp, 1998).

Table E.3. Distinction between emotional reactions, mood and temperament (adapted from Goldsmith, in Ekman and Davidson (1994)).

Aspects	Emotional reaction	Mood	Temperament
Temporal and other associations	Short-lived after removal of eliciting stimulus	Episodic and often related to a series of events with a particular quality	A general disposition or trait of the individual, activated by particular contexts

Cognitive components	Stimulus appraisal and election of a particular behavioural response	Management of emotions and stimulus attribution	Interacts with a wide range of cognitive processes during development to produce personality
Antecedents	Species-typical or learned stimuli of personal significance	Cumulative effect of emotional reactions and endogenous biochemical states, such as diet or chronobiological effects	Genotypic and early experiential interaction
Universality versus individuality	Universal species-typical phenomenon	Universal states, individualized with respect to management of emotions	Contributes to the definition of individual differences
Development	Specific reactions develop at different early life stages	Unknown	Organization and stability emerge, especially duration maturation

Emotional reactions, mood and temperament

Emotional processes are not just immediate reactions, but have a more pervasive effect on behaviour, and they may be distinguished on the basis of their temporal stability. From an evolutionary perspective, the advantage of biasing attention, **perception**, **cognition**, **arousal** and behaviour according to prevailing conditions in the immediate, medium and longer term is quite clear. An emotional reaction may be considered the immediate affective response to a new situation, while a mood may be considered a particular emotional predisposition to behave in a certain way over a longer time span, and **temperament** may represent a trait that describes the affective style of an individual and is the stable emotional process. Although this distinction between these three emotional processes may be considered somewhat arbitrary, it may, none the less, be conceptually useful (see Table E.3).

Moods are less clearly defined than specific emotional reactions, and some suggest there are basically only two moods (a positive, optimistic, one and a negative, pessimistic, one). Moods generally last longer than specific emotional reactions and are less closely associated with antecedent events or such intense arousal and expression, but they still play an important role in biasing cognition, shifting information-processing priorities, to bias perception and potentially the accessibility of information and emotional reactions that are relevant, or not, to the underlying mood state. Thus, within a negative mood state, the negative attributes of a situation may be accentuated: there may be a bias to behave either negatively or cautiously, and access to positive memories may be reduced. Experimental

P.217

methods used to assess mood have tended to focus on biases in perception, the retrieval of information and cognitive flexibility, e.g. **cognitive bias tests**.

Temperament includes a particular emotional predisposition within the individual, and there has been much work on the identification of temperament traits in animals and their physical correlates - for example, with laterality and the distribution of hair whorls. Although the temperament of individuals may be classified using a range of terms relating to their emotional response in different situations, many of these can be traced to differences in the sensitivity of three interconnected emotional systems that are linked to environmental reinforcement (Gray, 1991).

These go by various names, but basically involve a system that: (i) responds to signals of reward or the termination of punishment (Behavioural Approach System, Behavioural Activation System, Behavioural Facilitation System, Foraging/Expectancy System or Seeking System); (ii) responds to positive punishment and non-reward (Fight-Flight System or Behavioural Aversive System); or (iii) responds to signals of punishment, signals of non-reward, innate species-typical fear stimuli and novelty (Behavioural Inhibition System). This system functions as a comparator that stops ongoing behaviour when there is a discrepancy between what is predicted and what is detected in the environment.

All three systems have a neuroanatomical basis with predictable emotional outcomes from their activation. The Behavioural Approach System consists of dopaminergic projections from the midbrain to the basal ganglia and both their thalamic nuclear and neocortical associations, which make up the caudate motor system and *accumbens* motor system. The system is usually tonically active and may create the emotions that underpin hope, happiness and optimism. The Fight-Flight System consists of the *amygdala*, medial **hypothalamus** and central grey area. Activity within this circuit produces the emotions associated with defence, which may be felt as panic, rage or pessimism. The Behavioural Inhibition System lies within the septohippocampal system. Differences in the operating level of this system may be responsible for variations in trait anxiety, while specific activation may result in a more specific anxiety response.

It is suggested that other emotions may arise as a result of the blending of differential activation of these systems in specific contexts, in much the same way that the blending of activity in different retinal pigments results in the sensation of colour. However, some authors, e.g. Panksepp, propose a wider range of emotional circuits derived from evaluation of social situations, which may be particularly relevant to cognitively complex gregarious species including primates and nonprimate species such as the rat and the dog.

Enculturation

Culture may be defined as a set of behaviours that is not species-specific, but only displayed by some animals in a **group**, one **social group** or a population. This set of behaviours is transmitted through some form of **social learning**, and the term enculturation describes the process by which an individual acquires these behaviours. Traditions are considered precursors of cultural differences and refer to behaviours that are transmitted through some form of imitation. Culture and tradition in animals have become topics of intense investigation in recent decades, since scientists realized that large differences between individuals or populations of the same species may exist in their behavioural repertoire (**see: Individual differences**).

One of the most popular and early systematic observations on the development of a cultural behaviour in animals is potato washing in Japanese **macaques** (*Macaca fuscata*). Japanese researchers were giving sweet potatoes to a troop of Japanese macaques on the beaches of Koshima Island, off the coast of Japan, to habituate the monkeys to their presence and start behavioural observations of them. They observed a 1.5-year-old female (later named Imo, which means 'potato' in Japanese) bringing a potato to the nearby river, then dipping it into the water to remove the sand from the potato before eating it. Imo's mother and sibling soon started to display this behaviour after having observed Imo and, over time, the whole troop mastered potato washing. Koshima macaques have also learned to wash the potatoes in sea water to add salt to them, or to wash wheat in water to remove the sand more easily (as the wheat floats up to the top, it can be picked out without sand).

Culture and tradition are currently intensively studied, particularly in primates, to understand the social, environmental and cognitive factors that affect their occurrence and transmission. A growing body of data is showing that behaviours that can be defined as culture or tradition are common in several animal species. Animal dialects (e.g. in bird songs), fidelity to migration routes, the capacity to incorporate a

new skill to extract a given food item, or differences in the behavioural repertoire used to attract a mating partner or to catch a prey are all examples of behaviours that can be defined using the term 'culture'.

P.218

The development of some of these cultural differences or traditions probably does not require complex cognitive abilities. However, at least with respect to **tool use**, animals may need to possess some capacity to causally link a behavioural sequence with an outcome. This may be the case, for example, for a great tit (*Parus major*) opening a milk bottle with a stick or for a chimpanzee (*Pan troglodytes*) using a stick to catch termites (i.e. termite fishing). This sequence of behaviour may be reinforced through a trial-and-error process that does not require any conscious capacity to plan an action ahead. Recent findings, however, indicate that chimpanzees are very selective in their choice of tools to be used for a given task (e.g. termite fishing or nut cracking) and, when found, they can bring a tool with them for hundreds of metres or several minutes before reaching the place where they are going to use that tool. These observations suggest that, at least in some species, advanced planning, mental mapping and object manipulations may occur and that they are not skills that are exclusive to human beings.

During the enculturation process, several factors have to be considered. The diffusion rate of a particular behaviour (i.e. how quickly a new behaviour spreads in a group) may depend on how often animals encounter each other and how close they are during these encounters, or on the size of the social group and its cohesion, as all of these factors affect the occurrence of imitation and social learning. The spread of some cultural behaviours, such as a new extractive method to obtain food, may also be affected by the number of 'scroungers' in a group - that is, the number of animals obtaining food using the work of others. The identity of the animal that first displays a new behaviour may also affect the diffusion rate. For example, the diffusion rate may be faster if a new behaviour is displayed by a dominant individual, as the process will be at the centre of the group and thus there will be more chances for imitation.

Finally, the number of relatives an 'inventor' or 'expert' has may affect the diffusion rate, as imitation is favoured among relatives. Contrasting results are currently available on which animals are more likely to develop new behaviours. Some studies suggest that juvenile and/or subordinate animals should be more likely to become 'inventors' of a new behaviour, particularly in relation to food extraction, as these animals are usually prevented by older and/or more dominant animals from accessing rich and energetically plentiful food patches, or they may develop new social skills to obtain some benefit. Other studies indicate that the reverse may be true.

An elegant experiment on enculturation is the study conducted by Victoria Horner and colleagues on chimpanzees (Whiten *et al.*, 2005). They used three groups of captive chimpanzees and one apparatus ('pan pipes') from which the animals could gain food through the use of a stick and using two distinct techniques (i.e. 'poke' and 'lift' techniques). Horner and colleagues trained the dominant female in the first group to gain food from the apparatus using the 'poke' technique and the dominant female in the second group to gain food using the 'lift' technique. These two females were isolated from their group during training so that no other animal could observe them gaining food from the task. The two females were released back into their group when training was completed. No animal was trained in the third group. Horner and colleagues found that all the animals in the group where an 'expert' was available quickly learned how to gain food from the apparatus and consistently followed the technique used by the 'expert', even though some animals managed to discover by chance the other technique. No animal in the untrained group discovered how to gain food from the apparatus. These results indicate that social learning is essential for the diffusion of such cultural behaviours. Moreover, they show that chimpanzees tend to conform to cultural norms similarly to humans.

Endangered species

For many, the typical 'endangered species' are animals such as **giant pandas**, struggling to exist in their shrinking habitat, **rhinoceros**, decimated by poaching, or the bald eagle, threatened by pesticides. Most endangered species, however, are not so charismatic, although they all contribute to the rich diversity of life on Earth.

Most people will recognize that the label 'endangered species' denotes that a species of animal or plant is so few in numbers that it is at risk of extinction, but the term also has a more formal, often legal, definition. The International Union for the Conservation of Nature (IUCN) has developed a system for designating varying levels of vulnerability to extinction, as have many countries, provinces and states around the world. The IUCN enlists the support of more than 10,000 scientists worldwide to review data and determine whether species are at risk. The results of these evaluations are published in the *IUCN Red List*, which in 2007 listed more than 16,000 species of animals and plants threatened with extinction.

The IUCN recognizes three levels of endangerment: **critically endangered**; endangered; and vulnerable. A designation of 'endangered' indicates that the species is at very high risk of extinction in the wild. The criteria for listing a species are strict and systematic and include, for example, evidence that the species numbers have declined by more than 70% in the previous 10 years and that this trend has been stopped or that the numbers have declined by more than 50% but the cause of reduction has not been removed, and the species is continuing to decline. Participating biologists also use several other criteria, such as geographic range and absolute population size, to determine species status.

The Endangered Species Act of 1973 in the USA - and similar laws in other countries - has played a pivotal role in the legal protection of endangered species. Using its own set of criteria not too dissimilar from those of the IUCN, the US Fish and Wildlife Service (USFWS) charges its biologists with listing endangered species and developing and implementing

P.219

plans to recover listed species. This form of legal protection prevents Federal agencies from jeopardizing endangered species and restricts 'take' (killing) and trafficking (as in the pet trade). The Act also requires that USFWS authorities take action to establish **conservation** programmes, with the goal of stabilizing populations to the point that the species will no longer require legal protection. A group of experts has convened in a 'recovery team' to develop and implement a conservation strategy or 'recovery plan'.

For species facing more immediate risk of extinction, recovery plans sometimes call for establishment of **captive breeding** and **reintroduction programmes** (e.g. the California condor), but more often they aim to protect the existing population in the wild, as well as the habitat on which it depends. In recent years

recovery plans have focused less on single species conservation, which have met with limited success, and have been replaced with multiple-species habitat conservation plans. The goal of these plans is to preserve entire landscapes and ecosystems that contain multiple endangered species, rather than piecemeal approaches sometimes associated with single-species recovery plans.

Endocrinology

Endocrinology is the branch of biological science that deals with the endocrine system of glands in the body and their secretions (hormones). The endocrine system functions as a signalling system, using hormones as signalling molecules that induce a response in target cells. Hormones are mainly transported from the secreting gland to the target organ via the bloodstream. Major specialized glands of the endocrine system include: thymus, **adrenal glands**, **pituitary gland**, **hypothalamus**, pineal gland, thyroid gland, parathyroid gland, ovaries and testes. Other organs of the body also have an endocrine function, including the liver, pancreas, stomach, kidneys, skin, heart, adipose tissue and striated muscle.

Hormones have a wide variety of functions and modes of action, and are important in regulating **growth rate**, metabolism, tissue function, puberty, development and mood. Hormones are classified into three types: **steroid hormones**; protein hormones (including peptide hormones); and amine hormones. Steroids are derived from cholesterol and include such hormones as cortisol, corticosterone, **oestrogen** and **progesterone**. Protein and peptide hormones are made up of amino acids (ranging from three to over 200 residues) and include such hormones as **growth hormone**, **oxytocin** and ACTH. Amine hormones are derived from single amino acids and include such hormones as **dopamine**, **epinephrine** (adrenaline) and **norepinephrine** (noradrenaline). Hormones act by binding to specific receptors located on the surface of the target cells and inducing a response within that cell. Within the animal behaviour and welfare field, hormones of all three types have been subject to widespread research, with perhaps the most researched parts of the endocrine system being the **hypothalamic-pituitary-adrenal (HPA) axis** (CRH → ACTH → Cortisol) and the hormones of the adrenal medulla (epinephrine and norepinephrine), both of which are implicated in an animal's response to **stress**.

Some of the major challenges involved in using endocrine measures in animal welfare research revolve around the sampling method. Direct measures of circulating hormones invariably involve taking blood samples. Depending on the method, this may involve restraining the animal and inserting a needle into a superficial blood vessel to collect a sample - all of which can induce a stress response from the animal. The animal can be catheterized under **anaesthesia**, which may allow serial samples to be drawn without as much restraint, although this may restrict the ability to keep the animal housed in its original group as the catheter may be subject to unwanted attention from pen-mates. Alternatively, hormones and hormone metabolites may be quantified in saliva, **urine** and faeces.

(JNM-F)

Endorphin

Endorphins - α -endorphin, β -endorphin and γ -endorphin are endogenous, morphine-like substances with a similar chemical structure and clinical function in analgesic effects as morphine (endorphin is a short term for endogenous morphine).

The endogenous endorphins do not cross the blood-brain barrier. In the **central nervous system (CNS)**, endorphins and their immediate precursor, β -lipotropic hormone (β -LPH), distribute in the **neuron(e)s** of the arcuate nucleus of the **hypothalamus** and the limbic system. Their fibres project to different nuclei within the hypothalamus, mainly to the periventricular region, and to several regions within the CNS, including the mesencephalic periaqueductal grey area, the thalamus, the septal area, the amygdala complex, the *locus coeruleus*, the raphe nucleus and the spinal cord (**see: Brain**).

Endorphins are the basis of a diverse system (i.e. the **opioid system**) associated with physiological functions and pathological disorders. The multiple functions of endorphins are dependent upon binding to their specific receptors, which are widespread within the CNS. Three well-characterized types of **opiate** receptors have been identified by both pharmacological bioassay techniques and radiolabelled opioid binding studies, and originally designated as μ - (μ), δ - (δ) and κ - (κ) receptors, as well as several subtypes within each class. Each of them has a distinct selectivity profile and a unique pharmacological profile. The three major classes of opioid receptors have recently been renamed OP1, OP2 and OP3 receptors, respectively, by an International Union of Pharmacology (IUPHAR) nomenclature committee. Another σ - (σ) receptor may also be present in the brain.

Through binding and activation of these receptors, endorphins play important roles in the interaction of an organism with different **stress** factors, providing anti-stress and pain relief effects, which affect behavioural and physiological **homeostasis**, such as eating, drinking, **thermoregulation** and energy metabolism, immunity, mental illness and mood, **learning** and **memory**, **reproduction**, general activity and **locomotion**, and other behavioural and neurological disorders, most of which are associated with the functions of the hypothalamus and the limbic nervous system.

P.220

The distribution of endogenous endorphins and opiate receptors corresponds to the CNS areas where electrical stimulation can relieve pain. As components of an intrinsic pain suppression system, endorphins are involved in regulating the pathogenesis of **pain**. An activated endorphin system triggers an endogenous **analgesia** cascade by: (i) modulating nociceptive signals within local circuits, such as in the dorsal horn of the spinal cord (the gate control theory of pain), resulting in reduction or inhibition of nociceptive messengers forwarded to the somatosensory system; and (ii) by increasing activity of the supraspinal cord pain inhibitory systems, such as those in the periaqueductal grey matter and the hypothalamus.

These functions of endorphins suppress pain sensation and, hence, increase analgesia by leading to an increase in the pain threshold and **hyperalgesia** (intensity of pain), as well as **allodynia** (pain elicited via activation of normally non-painful A β -fibres by a non-noxious stimulus such as touch). Analgesia and its correlations with the activation of the endogenous opioid system have been found in experimental animals that suffer from pain caused by various stimuli. Analgesia also can be reached following an intraventricular administration of endorphin, which directly activates opioid receptors on the neurons of the somatosensory system.

Endorphin, similar to other endogenous opioid peptides, is sensitive to different stress factors. Significant endorphin activation by increasing the synthesis of peptides in opioid-containing neurons and the transformation of the inactive form into an active one has been observed under various intense stimulations. Provoked activation of the opioid system is part of an organism's physiological or pathophysiological adaptive processes in response to stress. Several cellular mechanisms for endorphins in the regulation of the stress response have been identified through activity: (i) on the functions of the **autonomic nervous system**, affecting cardiovascular response to stress, such as **heart rate**, respiratory rate, **blood pressure** and temperature; (ii) on the functions of the hypothalamic-pituitary-adrenal axis,

affecting synthesis and release of stress proteins - including ACTH and cortisol; (iii) as neuroregulators, exerting their effect on the functions of other neurotransmitter systems, such as **dopamine** and **serotonin**; and (iv) on the functions of the other brain regions such as the thalamus, the septal area and the amygdala complex, which mediate a variety of behaviours such as **depression** and **aggression**. For example, brain endorphins and **enkephalins** reduce aggression in animals, as indicated by endorphin levels being negatively correlated with aggression scores, and highly positively correlated with attack latency.

In addition, endorphins modulate animals' acute response to social conflict with an aggressive, dominant counterpart. Following injections, endorphins ameliorate stress-induced behavioural changes. These results indicate that stress-induced enhanced activations of endorphins serve to counterbalance the effects of stress hormones. These processes diminish harmful consequences of frequent overstimulation by chronic stress, increase organism resistance to stressors and lead to physiological function normalization. In humans and animals, disturbances in the regulation of endorphins might lead to stress-related physical and mental illness.

Endogenous endorphin also acts within the brain to mediate reproductive function. Endorphins inhibit the release of **gonadotropin** secretion, such as **luteinizing hormone** (LH) release in the **pituitary gland**. There are several neuroendocrine mechanisms of endorphins in modulating reproduction: (i) acting directly on the pituitary *pars distalis*; (ii) influencing gonadal functions via the regulation of hypothalamic LH-releasing hormone (LHRH) release; and (iii) regulating other neurotransmitters such as dopamine and serotonin, both of which have tonic, inhibitory effects on **sexual behaviour** and reproduction. These results indicate that endorphins have an integrative role between hormonal and neuronal functions. Under stimulation, endorphin levels are usually increased, mediating the inhibitory influence of both acute and prolonged stresses on reproductive functions, and exhibiting a long-lasting influence on brain serotonin content and sexual behaviour. Following beta-endorphin injection, brain serotonin levels are significantly decreased, while sexual activity (**see: Lordosis quotient; Meyerson index**) is increased in experimental animals.

Endorphins play an important role in the regulation of feeding behaviour and maintenance of energy homeostasis. Opioid neurons in the hypothalamus are direct targets of leptin, an adipostatic hormone, in regulating energy homeostasis via integrating peripheral and central information. Endorphins stimulate food intake, increasing the incentive value of food as a primary reinforcer. Endorphins modulate eating and energy metabolism through regulation of the function of melanocortin, since both endorphin and melanocortin are processed from **pro-opio-melanocortin** in the opioid neurons and putatively co-released at axon terminals.

Finally, endogenous endorphins as modulators are also involved in the cross-talk between the nervous and immune systems, directly or indirectly through the HPA axis. Endorphins increase natural killer (NK) cell cytotoxicity and immune responses at the sites of **inflammation**. In stressful stimulations, activation of endorphins has inhibitory effects on immune cells.

(H-WC)

Engram

An engram is the hypothetical 'footprint' of a **memory** in neural tissue - i.e. the physical and/or biochemical alteration that is thought to occur in the **brain** in response to external stimuli during memory formation and which persists during memory storage.

(JNM-F)

Enkephalin

The endogenous enkephalins - met-enkephalin and leu-enkephalin - are a group of small peptides found within the nervous system. In the **central nervous system (CNS)**, enkephalins are synthesized from proenkephalin. Proenkephalin and enkephalin-containing **neuron(s)** are widespread in the CNS, including the hippocampus, the amygdala, the cingulate cortex, the entorhinal cortex, the septum, the *substantia nigra*, the **hypothalamus** and the spinal cord.

Enkephalins have multiple roles in the regulation of physiological and pathological processes, including **pain** processes. Enkephalins display analgesic effects by: (i) directly modulating the processing of nociceptive information in the local circuits, inhibiting the release of pain-related neuropeptides

P.221

such as substance P and calcitonin gene-related peptide in the dorsal horn of the spinal cord and the trigeminal nucleus of the brainstem, where the integration of nociceptive signals is located; and (ii) indirectly blunting the distressing affective components of pain by reducing psychological and physical **stress**-associated emotional and affective states.

The widespread distribution of enkephalins and their receptors throughout the limbic system and the hypothalamus indicates that the enkephalin system is a major regulating system in modulating stress and non-stress states. Through the limbic system, enkephalins affect **memory**, **emotion** and **motivation** via the regulation of neural transmission, such as inhibiting gamma-aminobutyric acid (GABA) release from inhibitory interneurons, resulting in increased excitability of neurons of the hippocampal and dentate gyrus. These changes may facilitate memory-associated long-term potential and its related **neuronal plasticity**.

In addition, enkephalins acting in the modulation of **learning** and memory may also occur through alteration of peripheral autonomic function. These autonomic afferents communicate with the memory trace in the CNS through central regular pathways. Enkephalins, as neuromodulators, co-locate with **dopamine** and regulate behaviour via the regulation of the striatal output pathway, and also regulate secretion of stress hormones via the **hypothalamic-pituitary-adrenal (HPA) axis**. These modes of action indicate that changes of the enkephalin system, including enkephalin and its receptors, may cause damage to the adaptive cellular mechanism underlying the response of the CNS to stressors.

Enkephalins such as met-enkephalin also function as immune modulators, linking both the nervous system and the **immune system**. Met-enkephalin is involved in humoral and cell-mediated immune reactions. Experimental studies have shown that enkephalins promote the proliferation of mouse splenocyte and the production of IL-2 and IL-6 in a dose-dependent manner. Thus, met-enkephalin appears to be an important immunomodulatory signalling molecule exerting regulatory actions concerning the expression of pre-inflammatory cytokines.

(H-WC)

Enrichment

Enrichment is a broad concept, which encapsulates any change to an animal's environment that leads to positive ramifications, and thus improved or enhanced **welfare**. Enrichment is frequently considered to stimulate captive animals, both mentally and physically.

The concept of enhancing the environments, and thus the lives, of captive animals was recognized and suggested as being beneficial by Heini Hediger in the 1950s (Hediger, 1955). However, efforts were not really focused until the work of Markowitz, who coined the term 'behavioural engineering', later known as behavioural enrichment. Markowitz suggested that captive animals were motivated to work for rewards, so he and his colleagues set up situations in which the expression of a desirable behaviour would be rewarded (Markowitz, 1982). This followed simple **operant** conditioning rules, whereby any behaviour that was positively rewarded would be more likely to occur in the future, and thus its expression would

increase (**see: Conditioning**). For example, to achieve the aim of increasing activity levels in four Diana monkeys, they were provided with a food reward after completing a complex series of movements around their enclosure. The monkeys quickly learned that if they performed this series of behaviours they would gain food, and so they became more active and obtained more food rewards. Much behavioural engineering was implemented to elicit species-specific behaviours, increase activity levels, offer cognitive challenges and provide an easy method of monitoring health.

Other researchers considered the assertion that captive animals were motivated to work for rewards as being **anthropomorphism**. It is now generally accepted that this phenomenon, termed **contra-freeloading**, is frequently observed, and captive animals are seen to actively work for a resource in their enclosure, even when it is also freely available. Behavioural engineering was more accurately criticized for creating **abnormal** behaviours; behavioural expression was not always linked to environmental context and sometimes occurred at abnormally high levels. Most of the arguments against behavioural enrichment were offered on the basis that an alternative, environmental enrichment, approach was superior.

Environmental enrichment aimed to provide captive animals with opportunities in their environment that would stimulate 'natural' behavioural expression. For example, to increase activity levels in the same group of Diana monkeys, the environmental enrichment approach would provide a large and complex enclosure. This would be intended to stimulate the monkeys to investigate and interact with their environment, and thus result in the desired elevated levels of activity. Naturalistic enclosures were thus integral, though not mandatory, to the evolution of environmental enrichment.

In many contemporary enrichment programmes both behavioural and environmental enrichment techniques are employed; for example, puzzle feeders are provided in a large, dynamic and complex enclosure. The two approaches are similar in their underlying mechanisms, but very different in their function. In contrast to behavioural enrichment, animals' responses to environmental enrichment can be variable in form and timing.

Enrichment aims

Much enrichment aims to promote in captive animals specific behaviours that are observed in their wild **conspecifics**, to include reduction of **stereotypies**, increase in general activity, improvement in physical fitness and enhancement of social interactions. In addition, it is hoped that enrichment will create situations that confer welfare benefits, for example by providing choice or opportunities to gain control over the environment.

Behavioural expression is determined by neural activity, and thus if enrichment can modify behaviour it is not surprising that **brain** morphology, development and function and associated neural networks are also affected. The cerebral cortex is associated with 'higher' cognitive processing - for example, problem solving or complex movement - and is more receptive to enrichment than other areas of the brain. Neurogenesis, the creation of new neuronal cells, can be promoted through the use of enrichment. This increases brain plasticity enabling greater adaptation to environmental change through improved **learning** and **memory**. Indeed, learning deficits in mice,

P.222

caused by lead exposure, can be reversed when given enrichment.

Enrichment can also affect an animal's interactions with its environment; for example, fearfulness has been shown to decline in animals given enrichment. The physical exercise associated with enrichment has also been shown to aid recovery from brain damage, illness and also the deleterious effects associated with **ageing**. To date, many studies identifying the greater benefits of enrichment have been restricted to laboratory and some domesticated species. It is likely that, as we continue to study the impact of enrichment, we will discover that its benefits go well beyond what we initially expect or see.

Types of enrichment

Enrichment comes in many shapes and forms. Categorizing enrichment into meaningful groups can help with its practical implementation and can also give an indication of its function. It has been suggested that enrichment can be subdivided into five elements, which are not mutually exclusive: (i) food-based - anything involving food; (ii) physical - any part of the animal's environment, be it permanent or temporary structures and objects within the enclosure; (iii) sensory - stimulating any of the animal's senses, including visual, olfactory, tactile and auditory; (iv) social - whether this be provided by animals or humans; and (v) cognitive - which requires problem solving to differing degrees of complexity.

Food-based enrichment

Many species have evolved to spend a large proportion of their day searching to process and eat food (see: **Foraging behaviour**). Captive environments are frequently restricted and offer few opportunities for foraging or **feeding**, and the food provided frequently requires little processing. So it is probably a fair assumption that many captive animals spend less time on, and express a lower diversity of, feeding and foraging behaviours than their wild counterparts. To this end, many feeding enrichments aim to prolong the feeding experience by making the acquisition of food more difficult, whether food is hidden, hard to obtain in a puzzle or, once found, is low in calories, requiring more food to be eaten. As animals are highly motivated by food, it is not surprising that these types of enrichments are among the more successful.

Foraging can be stimulated by simply hiding food in flooring substrates, log piles, cardboard boxes or paper sacks. Alternatively, processing the food can be made more demanding by putting food in puzzle feeders or wire cages. These types of enrichment have been shown to increase enclosure use, activity levels and behavioural diversity, while decreasing incidences of **aggression** and **abnormal** behaviours.

Food can also be presented in such a way that species-specific behaviours are required to obtain it. For example, researchers provided food for black and white ruffed lemurs on the roof of their enclosure, and also using suspended feeding baskets. These methods were successful in encouraging the lemurs to use the vertical space in their enclosure and gain food as they would in the wild, using suspensory feeding postures. Enrichment can also be used to provide animals with the opportunity to use tools to gain access to their food; **tool use** has been observed in some primate and bird species.

As much enrichment is food based, care needs to be taken that the provision of enrichment does not indirectly lead to more food being provided than necessary, with resultant obesity. As a rule, enrichment should use food from the animal's daily ration; alternatively, food low in calories can be used so that long periods of feeding can be achieved.

Physical enrichment

Good enclosure design incorporates enrichment through the inclusion of beams, platforms, ponds and anchors for fixing perching and other objects. Many of these features are permanent, but many of them can be modified with some imagination or moved to provide animals with a different environment. For example, a pond can be filled with water or different substrates, and small bits of food can be provisioned in either the water or the substrates. Also perching, the use of ropes, beams and/or branches, can be rearranged or renewed within an enclosure, essentially 'rejuvenating' the exhibit. Many species show a high level of motivation for privacy or hiding places within their enclosure. Leopard cats were observed to lie in hiding places within their enclosure when their urinary cortisol levels were high, which was considered as showing that, when stressed, the cats sought out privacy. When provided with hiding places, as well as perching, the cats displayed increased exploratory behaviour and reduced levels of stereotypical behaviours, relative to that seen in previously unenriched enclosures.

Another method used to provide privacy or protective areas within the group is the provision of vertical panels within an enclosure. The effectiveness of vertical barriers depends greatly on the species' natural history. In primates the ability to escape visually from one another reduces aggressive encounters in stump-tailed macaques, but increases aggression in pig-tailed macaques. In one study, both of these primates were maintained as single-male, multi-female troops, but the source of aggression (and thus social tension) was different. In the stump-tailed macaque group the males interrupted female-female aggression and, in the pig-tailed macaque group, the male initiated male-female aggression. Accordingly, the visual barriers reduced social tension and aggression instigated by the male, as the females were able to hide from him. However, an increase in aggression was observed when the male was prevented from dispersing aggression between females, as he was unable to see them all.

The variety of objects used as enrichment is vast, from hammocks for laboratory-housed mice to straw bales for broiler chickens and balls for common seals. The degree to which objects can stimulate interest and the longevity of this interest are both greatly affected by many factors, including individual and species differences, group composition and size, and enclosure features, including which objects are currently present. For example, a group of 28 chimpanzees was provided with an uprooted tree as an enrichment item and spent 41.9% of the first day interacting with it, but thereafter interaction declined to 3.5%, whereas simple objects, like cardboard tubes and coloured key rings, led to significant and long-term reductions in stereotypic wire gnawing (reduced by 40%) and aggressive head pecking and mortality (from 1.06 to 0.57%) in laboratory-housed mice and laying hens, respectively.

P.223

Sensory enrichment

Frequently we forget, as 'highly visual' animals ourselves, that animals gain information about their environment using many different modalities (**see: Signal**). In captivity we can easily manipulate the visual, olfactory, auditory and tactile information that animals' receive. With some imagination it is also possible to manipulate thermal, humidity and electromagnetic gradients and the tastes available to captive animals.

Despite the fact that many people seem to use sensory enrichment, there are few empirical studies of its effectiveness or benefits in the literature. It is not surprising that the senses we are familiar with are used most frequently, so reports of using visual, auditory and olfactory sources of information are common. Television and radio have been used with many different species and found to have a variety of effects, depending on the programme shown or the type of music played! Researchers provided chimpanzees with a variety of videotapes showing different scenes (chimpanzees, other animals and humans). It was unsurprising that single-housed chimpanzees watched the television more than those socially housed, though there was a lot of individual variation.

When using sensory information care needs to be taken. It is important that the information being conveyed is understood. In particular, when playing back conspecific vocalizations, what messages are you sending? It is essential that the context is known when the vocalizations are recorded. Equally, when providing olfactory information in the form of faeces, it is necessary to ensure that they are from known healthy animals and do not provide a route for the transmission of disease.

Social enrichment

Sources of social enrichment can be provided through cage mates, whether of the same or a different species, and people, whether keepers or visitors - although interspecific contact may not substitute for intraspecific enrichment and vice versa. All social enrichment provides dynamic and unpredictable sources of stimulation, which may be one of the most enduring and effective ways of delivering enrichment to captive animals. Within the laboratory industry there is a lot of evidence demonstrating the importance of

housing primates in social groups. As such it is accepted that the welfare of social animals will be enhanced in captivity if they are housed with conspecifics. Social housing has also been shown to enhance the impact of other enrichment methods. Social groups are inherently difficult to manage, however, as they provide a myriad of pressures that can result in stress or physical injury (**see: Social behaviour**).

Whether social interactions between different species are enriching or not again depends on many variables. Mixedspecies exhibits in zoos have been successful with some combinations of animals but not with others, so care needs to be taken when putting different species together. Choosing species with different ecological niches will reduce the likelihood of competition, and thus aggression. In some circumstances the presence of humans will be enriching to captive animals, but again this depends on many variables, from the attitude and personality of the human to the past experiences of the animals.

Cognitive enrichment

Enrichment can provide captive animals with a mental challenge, usually a complicated route to food. Much has been learned about the cognitive abilities of a wide array of species by providing them with enrichment. Enrichment devices are seldom the only source of food available; generally, other sources of food are available concurrently in the enclosure, or regular meals will ensure the animal does not 'need' to use the enrichment. So why do animals take up the challenge to use these cognitively demanding tasks? It may be that the food in the device is particularly favoured, or maybe undertaking the task is stimulating. It has also been suggested that animals are strongly motivated to seek out information from their environment, which can be provided by learning from enrichment (**see: Exploratory behaviour**).

Summary

Enrichment methods are highly variable, and their success cannot necessarily be generalized between species, or sometimes between individuals. Modifications to general housing and husbandry routine can result in enrichment; however, changes can be made and no visible change in behaviour observed, or stress may be increased. It is imperative, therefore, that any change made to animals' environment that aims to enrich is appropriately monitored. In some instances, enrichment may provide a more dynamic environment in which animals can display more choice within and control over their environment, which is hard to quantify and may not lead to obvious behavioural changes.

There is good scientific evidence that enrichment is extremely beneficial on many levels. Through its incorporation into a wide variety of housing and husbandry regimes, in farms, laboratories, zoos and for companion animals, the application of this knowledge improves animal welfare.

Environmental ethics

Environmental ethics undertakes to examine and articulate, from philosophical and ethical perspectives, our attitudes towards animals and nature, paying particular attention to how

P.224

human beings should relate to 'Mother Earth' and to certain non-human beings with whom they share the planet. Questions related to the kind of moral relationship we ought to have with wild and domesticated animals, plants, ecosystems, inanimate natural objects and the planet, respectively, are posed and debated. Topical concerns given serious consideration include climate change, sustainability, consumption habits, obligations to future generations, pollution, species extinction, deforestation, species and wilderness management, unbridled agricultural expansion and thoughtless land development, human overpopulation and world poverty, and the respective local and global policy frameworks and institutions best suited to address these concerns.

Environmental ethicists come in many forms. Animal liberationists and protectionists typify *individualism*. Individualism is the view that only individuals (like sentient creatures) should be the proper focus of direct moral consideration. Holists, in contrast, contend that moral concern should be directed at the level of species or ecological systems rather than at individuals. A healthy debate continues between environmental ethicists and proponents of animal welfare and **animal rights** on whether the interests of individuals should remain subordinate to concerns related to the preservation of biotic communities. Notable scholars embroiled in these issues include Baird Callicott, Mark Sagoff and Bryan Norton.

Another way in which debates in environmental ethics are framed is in terms of human-centred perspectives (or **anthropocentrism**) and bio- or ecocentrism. Biocentrists contend that human beings are one among many interdependent members of Earth's community of life and that human beings have no greater inherent worth relative to other organisms. Another variant of this view, 'enlightened' anthropocentrism, contends that by spotlighting obligations to future generations of human beings we might help to curtail unrestrained and thoughtless use and misuse of Earth's resources.

Other notable environmental ethics include the land ethic and its contemporary offspring, deep ecology, coined by Aldo Leopold and Arne Naess, respectively. Leopold argued that our desire to control and conquer nature might be moderated if we identified with nature and habituated the norm that 'a thing is right when it tends to preserve the integrity, stability and beauty of the biotic community. It is wrong when it tends otherwise.' A parallel critique of the tendency to dominate nature is also made by

ecofeminists like Karen Warren and Val Plumwood, who argue that there is a correlation between the former and the domination of women and other vulnerable individuals or groups in society.

Epidemiology

Epidemiology is the study of the factors that influence health and disease at a population level. Epidemiology combines biology, clinical medicine and statistics to elucidate the **aetiology of diseases** or illness. Epidemiological techniques have not only been applied to examine illness and disease in animal populations, but also more broadly in the field of animal welfare, for example to study risk factors for behavioural problems. In many cases, **health** and **welfare** are intrinsically linked, and thus the gaining of a clearer understanding of the factors that cause illness or disease in animals also elucidates factors that impact the animal's welfare.

To carry out an epidemiological investigation, a number of different methods may be employed: surveillance and descriptive studies are used to study distribution; and analytical studies are used to study determinants (causes, risk factors). Surveillance can be defined as the systematic collection (usually involving survey), orderly consolidation and analysis of data, with prompt dissemination and feedback of the results to those who need to know, particularly those who are in a position to take *action*. Descriptive studies may take the form of case reports, which may document characteristics of individuals, and ecological studies, which may compare characteristics of populations. Surveillance and descriptive studies can be used to generate hypotheses about the illness (or welfare parameter) of interest and suspected causal factors, which can then be tested using analytical studies, such as observational studies (including cross-sectional, case-control and cohort studies) and experimental studies.

Epidemiological techniques have been increasingly used in farm animal welfare in particular, where relatively large populations of genetically similar animals may be kept in diverse housing systems. Surveys of farmers have yielded useful information about risk factors associated with such measures as lameness, abnormal behaviours and morbidity and mortality. Epidemiological techniques are also being used in the development of on-farm welfare assessment systems (see also: **Farm assurance scheme**).

(JNM-F)

Epigenesis

In modern evolutionary theory the term epigenesis refers to the phenotypic development of an organism or structure as a result of the interaction between the **genotype** and the environment. It contrasts with the theory of preformation, which states that the development of an organism is predetermined and not affected by environmental variables.

(BM)

Epinephrine

Epinephrine (adrenaline) is classified as a **catecholamine** and acts as both a neurotransmitter and a neurohormone. Upon stimulation of the **sympathetic nervous system**, epinephrine is synthesized and released from a small number of nerve cells in the **central nervous system** and a much larger number of cells in the medulla of the **adrenal gland**, which release epinephrine into the vascular circulation. Activation of sympathetic **neuron(s)** in the adrenal medulla causes the release of **acetylcholine** from nerves that terminate on chromaffin cells in the adrenal medulla. Receptor activation causes chromaffin cells to produce and release epinephrine and some **norepinephrine** into the blood. Epinephrine acts as an

P.225

agonist for α_1 -, α_2 -, β_1 -, β_2 - and β_3 -adrenergic receptors. However, the potency by which epinephrine can activate a receptor is less for β -receptors compared with α -receptors. Once epinephrine is released into the blood it can reach and affect all tissues possessing adrenergic receptors.

Epinephrine causes a multitude of effects that are both tissue- and receptor-specific. Through circulation in the blood, epinephrine can cause sympathetic effects at tissues receiving little or no direct sympathetic innervation, such as adipose tissue and blood cells. Almost all cells in the body have adrenergic receptors and thus the body is altered in a variety of ways when epinephrine is released into the circulation. Sympathetic activation occurs in response to stimuli associated with **fear, pain, anxiety** and **stress**. When released, epinephrine causes the following effects:

- increased heart rate;
- increased stroke volume;
- relaxation of vascular smooth muscle to increase blood flow to muscle and **brain**;
- constriction of vascular smooth muscle to decrease blood flow to the skin and intestine;
- mobilization of glucose from liver and fatty acids from adipose tissue; and
- stimulation of the conversion of glycogen to glucose in the liver.

Epinephrine has been measured and used in research to assess the **welfare** of animals. The basis for this measure is that an epinephrine release can be reliably produced when animals are subjected to **aversive** stimuli such as electric shock, **restraint** and **injury**. Furthermore, research with humans has shown that, when challenged with a mental test as compared with a physical challenge such as cold, epinephrine is released at a greater rate during mental challenges and norepinephrine is released at a greater rate during physical challenges. Thus, researchers have a tool that can indicate to what degree an animal is physically and mentally challenged by a potential stressor by measuring epinephrine and norepinephrine. However, reliable measurement of epinephrine has proved difficult; because epinephrine is released in response to nerve activation, its increase in the bloodstream is almost instantaneous.

Obtaining a blood sample from a research animal without the actual blood sampling procedure increasing circulating epinephrine is therefore challenging. Simply sticking a needle in the subject will increase the amount of epinephrine in the blood, thereby masking any effect of the situation that we are attempting to quantify. To avoid this problem, researchers have established protocols that fit animals with indwelling

catheters to allow blood collection without venipuncture. This alone is not enough, however, because the simple act of entering the animal's pen can cause epinephrine to spike. Gentle **handling** and training the animal to the procedure prior to blood collection, in combination with establishment of a jugular catheter, have been successful in allowing base concentrations of epinephrine to be collected.

Epinephrine has proved useful as one measure in assessing animal welfare; however, epinephrine is maintained at an elevated level in the body for only a very short time (measured in minutes). Assessment of chronic stress in research and production animals has relied more heavily on measurement of glucocorticoids.

(DCL)

Epiphenomenon

An epiphenomenon is something that is caused by something else but lacks causal powers of its own. It is unclear whether anything could meet this dual requirement, and in fact the term is often used informally to refer to an inconsequential by-product of a process. Epiphenomenalism is a rarely advocated theory in the philosophy of mind that treats mental states as causally inert products of physical activity.

(PAR)

See also: Consciousness

Epistemology

In philosophy the term 'epistemology' refers to the study of **knowledge** (**see also:** **Procedural knowledge**) - what it is, how we acquire it and what its limits are. Philosophers have found knowledge hard to characterize in general terms, and various theories of knowledge continue to have supporters. Most theories start from the insight that knowledge differs importantly from mere true belief: by guessing I might come to believe truly that it is exactly 4.29 pm, but I would not thereby know that it is 4.29 pm. The key question is then: what is required, in addition to true belief, if a person is to know that something is the case?

After this there is little consensus. Until well into the 20th century it was commonly assumed that a true belief becomes knowledge when the subject can *justify* holding it. However, in the mid-1960s it was shown that a person can be justified in holding a true belief and still lack knowledge. Two obvious options then opened up: one was to make the conditions of justification more stringent; the other was to look for something other than justification as the special feature of knowledge (e.g. to say that the true belief and the fact must covary in some way). Further problems ensued: stringent conditions of justification might imply that we know very little at all and, when the justificatory element is left behind, it can easily turn out that we know rather more than we take ourselves to know. Moreover, any condition will be hard to spell out in a way that is generally satisfactory.

Scepticism is the view that we suffer from a radical lack of knowledge, usually in a particular domain. Some domains of knowledge do seem to be more 'distant' than others: a belief that you now have an itch may seem more secure than a belief about the distant past, other people's minds and subatomic particles. The sceptic challenges us - often by pointing to the limits of what can be observed - to show that knowledge extends into these domains.

(PAR)

Equid

Equidae include Prewalski's horses (the Mongolian wild horse), domestic horses, African wild asses (and domestic donkeys), Asian asses, Grevy's zebras, common zebras and mountain zebras. They all belong to the order Perissodactyla (odd-toed ungulates), the suborder Hippomorpha and the superfamily Equoidea. It is believed that long-term geographic isolation of equid populations in the late Pleistocene led to the distinct species that exist today, with true horses (*Equus*

P.226

caballus) emerging from the Eurasian lowlands north of the great mountain ranges, while the asses occupied the arid zones of Asia.

(PDM)

Ethics

Broadly speaking, ethics is the systematic study of values, virtues, moral concepts, principles and/or practices as a way of helping us to determine what we ought to do. Ethics is not about who can scream the loudest during a verbal dispute, nor is it simply a matter of feelings, tastes or preferences. Instead, ethics deals with justifying or thinking through one's point of view in a principled way.

Ethics may be divided into the private/individual and public/social spheres or domains. While they are distinct, they certainly overlap. The private/individual sphere involves questions directed at the individual moral agent, e.g. 'What should I do about the treatment of animals in my laboratory?' Here, individuals may be assigned responsibility for performing harmful actions and receive praise for performing beneficial ones.

Ethics in the social sphere involves questions related to the nature of *our* public policies, laws and regulations, i.e. how the aforementioned should be established and promoted as the basis of a good society. Here, the attention is to social structures and their consequences and typically involves the distribution of goods by various state, civic or commercial institutions. Questions such as 'What ought I to do to bring about just or fair regulations?' and 'How should I challenge morally unjust social policies or regulations?' reflect the continuity between the personal and social domains of morality.

According to one influential view, ethical principles are *action-guiding* in nature and take the form of 'should'. For example, 'One should take proper care when experimenting on canines'. Scientific principles are *informative* in nature and take the form of 'can'. For example, 'When subjected to high levels of ammonia, pigs can experience irritated throats and eyes and suffer from lung damage'.

Ethics is not coextensive with or identical to the law or religion, but can certainly inform both these domains of human life. That is to say, we can separate legal questions from ethical ones, i.e. legal: 'What *does* the law say about experimentation using primates?'; ethical: 'What *should* the law or regulations say about experimentation using primates?'

Likewise, we can make the distinction between religious and ethical questions. For example, religious: 'How do the respective faith tenets in **Hinduism**, **Islam**, **Christianity**, **Buddhism** or **Judaism** say we must treat livestock?'; ethical: 'What ought members of a pluralistic society say about the moral status of livestock and how they should be treated?'

With the foregoing discussion in mind, we can construe animal ethics as follows: it is the systematic study of how we ought to relate to non-human animals (including domesticated and wild species). More specifically, it is the careful endeavour to determine our responsibilities or duties towards non-human animals (which need not have a legal or religious basis) and to establish principles that serve to guide our moral interactions with them (from the spheres of both private and social ethics). When inquiring into the nature of our obligations towards animals we should pay particular attention to the following: (i) What are the reasons given in support of someone's (and our own) view that animals have moral standing or that they do not? (ii) Are there moral principles (or action-guiding rules) that are implied by this reason or set

of reasons?; (iii) What are the attractive features associated with this view?; (iv) What are some short-comings?; and (v) How does our treatment of animals reflect good or exemplary moral character?

Animal welfare is unlike other areas of science in that the primary motivation for this field of enquiry is often based on the view that we have direct moral duties to animals rather than being a result of scientific curiosity. Thus, our notions about the proper treatment of animals are influenced not only by the empirical findings about animals but also by our ethical values. Our ethical values have evolved over time to include a growing concern for animals and what matters to them. Animal science has contributed immensely to ethical enquiry into the nature of our obligations to animals as well. Knowledge about anatomical similarity, biological functioning and a deeper appreciation of the mental lives of animals have all contributed to a better understanding of how animals can be benefited and harmed as a result of our actions and omissions. Careful ethical thinking and continued interweaving between these two fields of enquiry can also better shed light on other dimensions that influence animal **welfare**. This includes exposing the interplay between technological systems (such as housing and management practices), economics, regulation, ethical values, different conceptions and measurements of animal welfare, and knowledge about the animals themselves. One of the central debates in animal ethics concerns the moral status of animals. Conceptually, two broad views can be distinguished: extension approaches to moral status and community-oriented approaches to moral status.

Extension approaches

Proponents of extension approaches assume that the moral status of animals (and thus duties owed to them) hinges on whether they possess some essential characteristic or set of characteristics. These characteristics include the capacity for **pain** or pleasure, self-awareness and the capacity to have future-oriented projects. Apart from the noticeable disagreement among different camps regarding which characteristic should count as definitive for affording animals moral status, extension approaches also tend to offer 'a one size fits all' answer as to how we ought to treat animals, thus providing little genuine guidance in particular cases. The main accounts associated with the extension approaches include exclusive views and inclusive views.

Exclusive views

Exclusive views on the moral status of animals deny that animals deserve moral consideration in their own right. Two broad views include: (i) human-centrism - the main proponents being **René Descartes** and **Immanuel Kant**; and (ii) **contractarianism**, a leading proponent being Jan Narveson.

HUMAN-CENTRISM Proponents of human-centrism are committed to the view that human beings have dominion over the shape of animals' lives and, in particular, only those beings that have **consciousness**, reason and/or **language** should be afforded moral status and legal protections. As the argument runs, since only human beings possess consciousness, language and reason, they alone should be afforded moral status and/or

P.227

protected by legal rights. It also follows that it does not matter to the animals themselves how they are treated.

One consequence of this view is that animals have value only as a means to human ends. From an animal welfare standpoint, injuring animals, **hunting**, rodeos and confining animals for exhibitions should raise no moral eyebrows. The treatment of animals should be judged as being either moral or immoral only by virtue of its connection to human interests.

A general worry about human-centrism is that, if we exclude certain animals from the moral community because they lack language or reason, then we must also (as a matter of consistency) exclude some categories of human beings who do not possess either language or the capacity for reason or abstract

thought. Thus, human infants and certain nonparadigm human beings will also be excluded from being the recipients of moral respect in their own right. This certainly challenges our deeply held moral intuitions about who counts and who does not, from the moral point of view.

CONTRACTARIANISM A close cousin of human-centrism is contractarianism, which has an affinity to egoism. Jan Narveson, a contemporary Canadian thinker, is a main proponent of this view. According to Narveson, morality is a function of a contract between members (contractors) of comparable abilities or political-ethical 'powers'. Animals do not possess moral status or rights because they, unlike human beings, cannot be parties to a social contract that upholds certain reciprocal obligations. Once again, differences between animals and ourselves are highlighted as the basis of keeping animals out of the moral arena. On this view, it is presumed that only human beings can cooperate with and act in kind towards each other.

However, this view does not preclude having duties *about* animals, even if we do not have direct duties to them. These indirect duties are predicated on acting in ways that promote *our* own benefit. For example, we are required to refrain from injuring a cat, not because we think that it will harm the cat itself if we mistreat it. It is a moral affront to harm the cat because it results in harming the moral agent who is invested emotionally (for example) in the animal. We may also be worried that this co-contractor could take some legal action against us for injuring 'their property'.

Contractarianism suffers from the same concerns levelled against human-centrism. The capacities that are appealed to in denying that animals have moral status will also leave certain categories of human beings who are not contractors, like children and mentally incompetent human beings, as being undeserving of respect or protections in their own right. There is little incentive to regard these human beings as mattering for their own sake. Treating them with respect may matter only as a side condition to observing one's contractual obligations to other contractors to whom they belong.

Inclusive views

In contrast to exclusive views, inclusive views on the moral status of animals ascribe moral status to animals in their own right based on the animals' possession of certain moral statusmaking characteristics. Two broad views include **utilitarianism**, a key proponent of which is **Peter Singer**, and the rights-based approach, a key proponent being **Tom Regan**.

UTILITARIANISM Utilitarians consider the rightness or wrongness of an act to be determined solely by the consequences that will impact the well-being of the affected individuals. Singer contends that we should include the interests of *sentient* animals in our utilitarian calculations. To discriminate against them simply on the basis of species membership is tantamount to **speciesism**. He concludes that practices such as agriculture and biomedical research that employ animals should cease, since the suffering they inflict on animals is not outweighed by the benefits produced for all the affected parties.

The primacy of **sentience** as *the* morally relevant criterion is not uncontroversial. Some argue that Singer's criterion of sentience may be too simplistic as a moral category, since it fails to reflect our phenomenal experiences of animals by ignoring differences in quality and richness of life across species. There *are* morally relevant species differences between animals and human beings, including the ability to take responsibility for their actions, to reciprocate in kind and to desire self-respect.

Some utilitarians are considered reformists. Sensitive to the upward struggle to establish strong or equal moral status for animals relative to human beings, these utilitarians call for piecemeal changes within current systems where animals are used. For example, utilitarian reformists might call for more attention to disease modelling and enriched housing systems and for greater scrutiny of the appropriateness of techniques, endpoints and experimental design. This perspective is sometimes mirrored in work pioneered

by **Russell and Burch (1959)** on the **three Rs principle**, and often serves to underpin how many Institutional Animal Care and Use Committees function.

RIGHTS-BASED Taking a rights-based approach on the issue of inclusion, Tom Regan contends that, in contrast to utilitarianism, certain actions ought not to be done to morally considerable subjects or rights-holders, regardless of the goodness of their consequences. He argues that it is unethical to sacrifice the interests of morally considerable individuals in order to benefit others. The basis of Regan's argument is his notion of subjects-of-a-life. Subjects-of-a-life (including some animals) have inherent worth and deserve moral respect/have rights. They should not be considered or used as mere resources. Regan concludes that we should not use animals even if we do so humanely or if suffering is minimized - or despite a great benefit to a large number of people. He takes an abolitionist stance with respect to most forms of animal use.

One major criticism of this view is that the rights-based approach does not offer clear guidance on what we ought to do in cases of conflicts of rights. Some have criticized Regan's definition of subjects-of-a-life for its lack of specificity. If 'psychological identity over time' and 'sense of one's own future' are construed broadly they encompass almost any animal, including organisms like *Planaria*, in which case it is not a useful moral category. However, if they narrowly denote 'reflective self-consciousness' then they may be misapplied to most animals that Regan counts as subjects-of-a-life (Russow, 1988).

Another criticism of the strong **animal rights** view is that it lumps animals into one amorphous group with the same moral

P.228

identity. By emphasizing only species similarities and egalitarianism, the vital interests that moral agents or human beings uniquely have are ignored. Also, by de-emphasizing the 'humanness of animals', we might be better able to appreciate the natures of animals and devote our energies to promoting responsibilities based on care for the kinds of creatures animals are in and of themselves (Anthony, 2003).

Community-oriented approaches

In contrast to the extension models of the moral status of animals, community-oriented approaches contend that moral concepts (including the question of moral status) are a function of common enquiry and consensus negotiation, and should be applied on the basis of some form of community. Our circles of shared and mutual dependencies ground the basis of specific obligations.

This view is eclectic in scope in that it incorporates elements of interspecific equity and human virtues such as restraint and diligence, and promotes an intimate understanding of animals' points of view. It rejects the 'one-size-fits-all' application of a single abstract moral principle to the animals issue and encourages context or case-by-case specific analysis.

Some key shortcomings associated with this approach include worries about whether all the relevant parties will be represented in consensus dialogue or debate. Furthermore, since it must be determined antecedently who counts as a member of a community and why (in order to have a seat at the table, so to speak), it presupposes that we have already worked out the (quite controversial) basis of the moral status of animals beforehand. There are two categories of this approach: (i) ethics of care; and (ii) **communitarianism**. The main proponents of the former include Mary Midgley and Nel Noddings (see: **Relational ethics of care**), and of the latter **Bernard Rollin**.

Ethics of care

On the ethics of care front, moral obligations are a function of our relationships with others. Our sense of community or connectedness with others (including animals) is the basis of our ethical obligations to

animals. What is important is the discharge of responsibilities based on virtues of care, compassion and empathy, and not safeguarding of rights per se.

Worries about this view include the fate of animals that we regard as being within a social community - for example, certain wild animals or animals considered as 'pests'. Also, the notion of community is fluid and precarious, and hence the protections afforded to animals that may have once been considered members of the moral community - due to their proximity and high visibility - may wane in light of their physical remoteness and our emotional attachments to them (as in the case of terrestrial and aquatic animals raised for food).

Communitarianism

Bernard Rollin is a proponent of a social or consensus ethic, where rights and responsibilities are a function of an implicit social contract among human beings that stipulates mutual expectations for conduct (including the treatment of animals). Under Rollin's view, animals have a distinctive **telos** or 'nature', or central defining properties that capture the good of the being in question and form the basis for moral respect. In the case of food production and use of animals in research, Rollin argues that they are permissible so long as we minimize or abolish production systems that go against these animals' telos.

A general worry about Rollin's view of telos is that it is unclear whether or not animals' 'natures' are, in fact, metaphysically real properties, as he seems to suggest. The identity of distinctive animal natures remains controversial (especially given evolutionary theory that species (and their traits) are always in flux). Furthermore, Rollin's emphasis on respecting the telos of animals, and its conservative streak, may not go far enough in opposing traditional uses of animals or conditions that are not really good for their welfare. It also does not address very well the acceptability of changing the natures of animals through those genetic means that may bypass welfare concerns but that pose an affront to conceptions of animal integrity and dignity.

Ethogram

An ethogram was originally considered to be a list of the complete behavioural repertoire of a species. However, there are inevitable difficulties in achieving such a list for most species, since behaviour varies depending on environment and individual experience. In addition, the chances of reaching agreement on definitions of much of the complex behaviour exhibited by many species are slim, and so this concept of an ethogram is not particularly useful or practical. The current, more common, usage of the term is that an ethogram is a list of the types of behaviour performed by particular individuals in a particular environment (and usually derived for a particular purpose - see below). In addition to a list of behaviour types, an ethogram should include precise descriptions of each behaviour (see Table E.4).

It is absolutely fundamental to any study of animal behaviour to define what behaviour types are being observed and recorded, and therefore production of an ethogram is always the first step in any animal behaviour research. To produce an ethogram it is necessary to observe the animals for some time in order to become familiar with all the types of behaviours they perform and what purpose each behaviour appears to have. Sensible decisions can then be made as to how broad or narrow the behaviour categories need to be. Often ethograms include broad categories of behaviour that are subdivided into more precise forms of that behaviour, e.g. a

P.229

broad category might be **locomotion**, which could be divided into walking, running, climbing and jumping (see Table E.5). It is usually necessary, for the purpose of analysing data, to make each category of behaviour in an ethogram mutually exclusive, so the definitions must be written with care, e.g. for a ruminant the behaviour 'lying at rest' may be performed at the same time as 'ruminating', so needs to be defined more precisely as 'lying at rest, not ruminating'.

For behavioural research purposes it is important to classify each behaviour in an ethogram as a behavioural state or a behavioural event, as these require different recording methods to obtain an accurate estimate of how often or for how long they are performed. A state behaviour generally has a long (measurable) duration and includes behaviours such as rest, walk and feed. An event behaviour has a very short duration such as yawn, scratch or roar. Because state and event behaviours are usually recorded by different means and used in separate analyses, it is acceptable in these cases to include non-mutually exclusive states and events in an ethogram - e.g. a baboon may perform lying rest at the same time as yawning.

Table E.4. An ethogram developed to determine the broad activity budget of hamadryas baboons in captivity.

Behaviour	Description
Locomotion	Fast or slow, horizontal or vertical movement around the enclosure not including movements involved in another behaviour (e.g. play, aggression)
Immobile	Stationary standing, sitting or lying and not performing another behaviour (e.g. grooming)

Foraging and feeding	Searching for (e.g. in bark substrate), picking up, placing in mouth and chewing of food items, including chewing of wooden structures in the enclosure
Playing	Apparently functionless manipulation of objects or rapid movements such as running, somersaulting, etc. alone or with others
Grooming others	Grooming another individual
Being groomed	Being groomed by another individual
Autogrooming	Grooming self
Aggression	Any aggressive behaviour to another individual, including visual and vocal threats, chasing and fighting
Mounting	Mating behaviour - male mounts female with back feet on female's ankles

Table E.5. An ethogram developed to investigate changes in behaviour of captive blue duiker (*Philantomba monticola*) when moved to new enclosures.

Main category	Subcategory	Description
Rest	Standing rest	Standing inactive for long periods, not ruminating
	Lying rest	Lying inactive, eyes open, not ruminating
	Sleep	Lying inactive, eyes closed, not ruminating
Maintenance	Eat provided food	Intake of pellets/grain/fruit
	Eat provided browse	Intake of browse provided by keepers

	Eat enclosure browse	Intake of browse growing in enclosures
	Eat soil/insects	Licking/intake of unidentified items on ground
	Drink	Intake of water
	Urinate	Excretion of urine
	Defecate	Elimination of faeces
Ruminate	Standing rumination	Rumination while standing
	Lying rumination	Rumination while lying
Travel	Walk	Slow movement not accompanied by investigation of surroundings
	Run	Rapid movement not accompanied by investigation of surroundings
	Jump	Movement over an obstacle
Investigation	Explore	Slow movement accompanied by frequent pauses to sniff/look at objects and surroundings
	Pause alert	Short pause and observation of surroundings during exploration
	Sniff	Stationary sniffing at air or objects in enclosure
Groom	Standing autogroom	Scratch, with foot or teeth, or lick self while standing
	Lying autogroom	Scratch, with foot or teeth, or lick self while lying

Interact	Groom other	Scratch or lick other animal
	Groomed by other	Scratched or licked by other animal
	Reciprocal groom	Simultaneous groom other and groomed by other
	Rub scent glands	Pressing together of pre-orbital scent glands with other animal (blue duikers only)
	Scent mark object	Marking objects in enclosure with pre-orbital gland
	Genital sniff	Male sniffing at rear of female
	Chase	Fast movement after another animal
	Flee	Fast movement away from another animal

P.230

Ethograms for the same species may differ depending on the individuals, environment and, most of all, the purpose of the research. For instance, an ethogram for wild lions will probably include **hunting** behaviour, possibly broken down into more precise stages of hunting such as stalking and chasing, whereas, an ethogram for lions in a **zoo** is unlikely to include hunting since captive lions are generally not provided with live prey. Similarly, an ethogram for juvenile macaques will probably include **play**, but may not for adult macaques. Even in the same environment for the same individuals ethograms will differ depending on the research question. For instance, if the research question is 'Does group size affect aggression in mandrills?', then the ethogram will include many types of **aggressive behaviour** such as threat, display, spatial displacement and fight. However, if the question is 'Does group size affect activity levels of mandrills?', then the ethogram may only include one broad category, '**aggression**', or may even group aggression into a wider category of '**social behaviour**'.

Ethological relevance

Ethological relevance refers to stimuli that are relevant to an animal and how it behaves. That is, animals have evolved to respond in certain ways to certain stimuli and ignore other stimuli. When conducting animal behaviour experiments, it is important only to ask the animals to perform ethologically relevant tasks or to interact with ethologically relevant stimuli, as lack of response may not indicate inability to learn or a **cognitive dysfunction**.

(LMD)

Ethology

Ethology was defined by **Niko Tinbergen**, one of the founding fathers of the field, as 'the biological study of behaviour'. It is a word particularly applied to the body of theory built up by **Konrad Lorenz** and by Tinbergen in Europe during a period of about 40 years in the middle of the 20th century, culminating in their award, with **Karl von Frisch**, of the Nobel Prize for Physiology or Medicine in 1973. While much of that theory has been superseded, the approaches that they pioneered have had a lasting impact on studies of animal behaviour throughout the world.

At that time, most others who studied behaviour did so from a psychological viewpoint. The closest this came to ethology was the field labelled '**comparative psychology**' in the USA, but even this was limited in its perspective compared with ethology. Most psychologists then were particularly interested in mechanisms, especially of learning, and their primary aim was to shed light on human behaviour. To the extent that they studied animals, this was usually rats or pigeons in carefully controlled laboratory conditions, the aim being to discover fundamental laws of behaviour that could be generalized to human beings. The ethological approach was in stark contrast to this, with studies on a wide variety of species, often birds, fish or invertebrates, usually in as near to natural conditions as possible. Tinbergen's observations on the courtship behaviour of sticklebacks, and Lorenz's on imprinting in young geese, are well-known cases in point.

As biologists, the early ethologists were impressed with the diversity of nature and the wonderful ways in which the behaviour of animals is adapted to their particular ways of life. While they did develop general theories - for example, Lorenz's ideas about **motivation** - the evolutionary basis of behaviour and how it had led to differences between species was never far from their minds. The key role of genetics in leading to such differences led them to stress biological constraints on behaviour, often referring to the behaviour patterns they studied as 'innate' or driven by 'instinct'. Nothing could have contrasted more with the approach of psychologists, with their prime interest in learning, and this led to some sharp disputes, particularly in the 1950s.

In one of his most important papers, Tinbergen outlined the subject matter of ethology. He pointed out that, if one wanted to understand a particular aspect of behaviour, one had to seek answers to four different types of questions, those concerned with causation, function, development and evolution. To know the causes of behaviour one had to look at the mechanisms underlying it. What external stimuli

elicit it? What neural circuits are involved? How is it influenced by hormones and other aspects of the animal's internal state? Function is quite a different matter, for here one is interested in what use the behaviour pattern is to the animal that shows it. What is its selective advantage? How does it enhance the animal's **fitness**? Questions about cause and about function are both important, but they are very different and also demand totally different answers. A male fish may court because he has **testosterone** in his bloodstream (cause) *and* because this behaviour attracts females to mate with him (function). We need to answer both sorts of questions and also keep them separate in our minds, for light cannot be shed on questions of one sort by answers of another.

Beyond these two primary questions, sometimes referred to as ultimate questions (function), as opposed to proximate questions (causation), are the two others: How does the behaviour develop during the lifetime of the individual? From what was it derived during evolution? The developmental question concerns when the behaviour appears and what particular experiences, if any, shape it. For example, does the animal copy other individuals? The evolutionary question looks at the derivation of the behaviour during the course of evolution. If a male shows a particular display, what normal everyday activities might it be derived from and why might females respond positively to these so that selection favoured their evolution into more striking and stylized displays?

At the time when Tinbergen outlined these questions, all four of them were active subjects of study. While Lorenz occasionally referred to development as a subject for embryologists, his own studies of **imprinting** were a counter-example.

P.231

Both he and Tinbergen generated models of motivation to try to understand why animals sometimes do one thing and sometimes another, an issue central to understanding causation. Lorenz's comparative study of the displays of ducks, geese and swans was a fine example of how evolution had shaped the behaviour of animals, and the experiments of Tinbergen on eggshell removal by gulls are classic examples of how the scientific method can be applied to answer functional questions.

In his book *Sociobiology* in 1975, **E.O. Wilson** predicted that 'ethology and comparative psychology ... are destined to be cannibalized by neurophysiology and sensory physiology from one end and **sociobiology** and **behavioural ecology** from the other'. In many ways this prediction has come true. Studies of causation at the behavioural level now receive much less study than they did in the 1970s, and this is partly because of the rise of '**neuroethology**', work aimed at understanding mechanisms of behaviour at the level of the nervous system. On the other hand, behavioural ecology, the main focus of which is understanding the adaptive significance of behaviour, has become the major focus of studies at the behavioural level.

While these changes have somewhat eclipsed the rounded approach outlined by Tinbergen, there is recent evidence of a swing back, with the increasing realization that the adaptiveness of behaviour is limited by causal and developmental constraints. Thus, while it is true that the detailed theories put forward by the early ethologists receive rather little attention today, their general approach to studying the biological basis of behaviour has left a rich legacy. The bald dichotomy between what is learned and what is instinctive has been left behind. Studies of animal behaviour today, by both biologists and psychologists, are concerned with a wide range of species in the field and in the laboratory, and have been greatly enriched by the perspective that the pioneers of ethology provided.

Ethopathy

An ethopathy is a behaviour not found within the **ethogram** of free-ranging members of the species. As such, an ethopathy may be considered a form of **abnormal** behaviour. An ethopathy may be a behavioural problem, but behavioural problems are not necessarily ethopathies. It has been suggested that the occurrence of ethopathy is a cause for concern deserving of scientific attention to evaluate its **welfare** significance.

(PDM)

Eugenics

A distinction is usually drawn between positive eugenics - the deliberate selection of desirable physical and behavioural traits - and negative eugenics - the attempt to 'breed out' undesirable characteristics through prevention of reproduction by means of **castration** or sterilization. During the 19th and early 20th centuries, eugenics was widely influential in policies aimed at human improvement, but was discredited by Nazi abuse, although it still persists in racist propaganda and behavioural genetics.

The scientific development of eugenics has its roots in the 19th century. It involved improvement of the inherited characteristics of a species by deliberately multiplying desirable qualities and eliminating undesirable ones through selective breeding. It was largely assisted by the emergence of the science of statistics, as formulated by the German mathematician Carl Friedrich Gauss, and applied to a variety of empirical observations of plant and animal propagation.

(DL)

See also: **Breeding**

Euphagia

Euphagia, or the exhibition of **nutritional wisdom**, involves selection of suitable diets through the detection of nutritional or anti-nutritional properties of feeds and comparison with body status of specific nutrients or toxins. Thus, when an animal becomes deficient in a particular nutrient, such as sodium, it is suggested that it will develop a hunger for that nutrient that will attempt to cause the animal to search for it and replenish body levels. Such an ability could easily be inherited, either genetically or from exposure to postingestional signals *in utero*; there is evidence of both mechanisms. However, the neurological requirement to recognize and correct deficiencies of all the major nutrients would be very great and is unlikely to exist. Indeed, avoidance of toxic elements in feeds is notoriously imprecise and often results in poisoning of stock when suitable alternatives are not available. To date, an ability of some animals to select feeds high in energy, protein, sodium, calcium and iron has been detected in a variety of

species, mostly domestic, and avoidance of the toxic elements lead and cadmium in feeds demonstrated in domestic ruminants.

(CJCP)

European regulation of animal welfare

Regulation of animal welfare across Europe operates both through agreement to conventions produced by the **Council of Europe** and other international bodies such as the Organization for Economic Cooperation and Development (OECD) (**see: International regulation of animal welfare**) and the enforcement of instruments introduced through the European Community (EC) in the form of primary legislation, such as treaties, and secondary legislation, such as regulations, directives and decisions. European law has established 'four freedoms' relating to cooperation between states; this includes the ability of members to market freely across the EC.

From an animal welfare point of view, this meant there could be no restriction or veto on meat from countries where animal welfare was not as high as in the nation importing the meat, although the concept of higher welfare standards producing a different and higher-value product that can be protected by law is being pursued by some. The Treaty of

P.232

Rome in 1957 brought in the Common Agricultural Policy, which was seen as a 'cash cow' for overproduction. Reform means that links between production and subsidies have lessened, with more available for animal welfare and environmental protection.

For a considerable time, animals were considered in European law as merely articles of trade. The Treaty of Amsterdam, in force from 1999 and brought in by Protocol, introduced the idea of animals as 'sentient beings', with member states required to have 'full regard to animals' welfare'. However, this was weakened by the proviso of exceptions for national customs and religious and cultural rites, thus still allowing, for instance, **bullfighting**.

(BG)

Eusociality

Eusociality is the most complex form of sociality and is characterized by the cooperative rearing of young, an overlap of generations and specialization between reproductive and one or more sterile castes that specialize in foraging or parental care (workers) or defence/attack (soldiers). Eusociality is most commonly found in the Hymenoptera (ants, bees and wasps), but is also evident in some termites, aphids, thrips, shrimps (*Synalpheus*), a species of beetle (*Austroplatypus incompertus*) and two mammalian species of mole rats, although inclusion of the latter depends on how strictly eusociality is defined: in the narrow-sense definition, the irreversible development of nonreproductive castes would exclude the mole rats. The evolution of sterile worker castes has been used to challenge the concept of Darwinian selection (**see: Darwin, Charles; Evolution**).

The most widely held view is that eusociality evolved via **kin selection**. Essentially, by helping close relatives raise additional offspring, the sterile castes can increase the frequency of their genes in the next generation through the production of non-descendent kin. This may be their only 'reproductive' option, as their ability to produce descendent kin is limited by ecological constraints or reproductive suppression by the queen. In some respects, the non-reproductive workers are analogous to the somatic cells of an organism: the cells themselves do not pass on copies of their genes, rather they function together to transmit their genes by proxy, via the germ line cells.

(PE)

Eustress

Eustress, literally meaning good **stress**, is a positive form of stress or a stress that may be perceived as pleasurable. Eustress can have similar physiological effects on the body as **distress**, such as increased **heart rate** and elevated **glucocorticoids**, which in themselves are not necessarily harmful to animals. Examples of eustress include copulation or running during a play bout.

(LMD)

Euthanasia

Literally meaning a good death (from the Greek *eu*, having a connotation of goodness, and *thanatos*, death). When applied to animals it is usually applied to the means by which an animal is killed, rather than the reason for it being killed (the human sense). Acceptable methods should normally cause a rapid loss of consciousness, be painless, not cause discomfort or distress, e.g. through being aversive or unpleasant in some way, be aesthetic to the person carrying the procedure out, be easy to perform, be repeatable without loss of efficiency and be minimally invasive. Methods may be divided into inhalant methods, non-inhalant pharmaceutical agents and physical methods. In some cases, one method may be preferred for social reasons, e.g. the increasingly common use of lethal injection to induce euthanasia in horses in preference to shooting, as this is less distressing for the owner. There are reasons why some acts of euthanasia, regardless of the method, may be unacceptable (the human sense), such as **breeding** more animals than one needs for research resulting in a surplus that has to be killed, and killing animals in ways that cause avoidable **suffering** for ritual reasons.

Evolution

Nothing in biology makes sense except in the light of evolution.

T. Dobzhansky

In the early 1800s, species were viewed as immutable entities that did not change from the time they were created until they became extinct. Variation among individuals within a species was considered to be unimportant - imperfections around an ideal form. This view is known as essentialism. Essentialism can be traced back to Plato and was thoroughly incorporated into Christian theology. Fossils, under this view, were assumed to be species that had gone extinct. New species were thought to be created *de novo* (from scratch).

Jean-Baptiste Lamarck (1744-1829) was one of the few in his time to suggest that species evolved. Lamarck viewed fossils not as extinct species but instead as ancestral forms of modern species. He hypothesized that 'lower' forms arise through spontaneous generation and gradually evolve into 'higher'

forms because of an intrinsic drive towards increased complexity. The great diversity of life forms was a consequence, he argued, of organisms adjusting to environmental conditions within their lifetimes and transmitting these modifications to their offspring (inheritance of acquired characteristics). Thus, Lamarck's theory could account for the overall trend towards increasing complexity in the fossil record and the observation that organisms are usually well adapted to the environments in which they are found. All that would be required would be vast amounts of time.

Geologists in those days had already concluded that the earth was millions of years old (the modern estimate is 4550 million years), and they knew that fossil species were found in a succession of sedimentary layers corresponding to different geological periods. For example, fish first occurred in the Silurian, reptiles in the Carboniferous, mammals in the Triassic, placental mammals in the Cretaceous, and so on. These patterns were repeated around the globe. Nevertheless, geologists were quite adept at reconciling their findings with the prevailing essentialist view. Lamarck's theory was rejected,

P.233

but largely for the wrong reasons. The geologists correctly pointed out that simpler forms often replace more complex forms in the fossil record, which contradicted Lamarck's notion that complexity increases over time within lineages. We also know now that characteristics acquired during an individual's lifetime generally are not passed on to offspring (with some important exceptions, such as culturally inherited traits). Nevertheless, Lamarck deserves credit for proposing the first coherent theory of biological evolution.

Charles Darwin himself was a geologist, so he knew a great deal about fossils, but this is not what turned him into an evolutionist. In 1831, at the age of 22, he took a 5-year voyage as the naturalist on the HMS *Beagle*. The crucial observation he made on that voyage was that species varied so much from place to place that it was impossible to draw clear distinctions between species and varieties within species. For example, mockingbirds in the Galapagos differed so much from island to island that the ornithologist to whom Darwin shipped specimens was compelled to call them separate species. Intraspecific (within species) geographic variation clearly conflicted with the conventional wisdom that species were distinct and immutable, with only random variation around ideal forms. Darwin rejected the idea that species were unchangeable, and began to suspect that one species could evolve into another. That sent him in search of more evidence and a mechanism.

Some of the kinds of evidence that Darwin gathered are listed below. Not all of these specific examples were available in Darwin's time. Absent from this list are categories of evidence discovered after Darwin's time, such as modern molecular genetics.

Convergent forms

Different kinds of animals occupy similar ecological roles on different continents. The comparison of Australian marsupials to placental mammals elsewhere in the world is a classic example (marsupials are mammals in which the young are born at a very early stage of development and carried in pouches). In their external features, marsupial moles closely resemble placental moles, marsupial mice resemble placental mice, marsupial flying phalangers bear a striking resemblance to flying squirrels, and so on. Despite these outward similarities, however, all marsupials are more similar to each other skeletally, reproductively and genetically than they are to any of the placentals. This kind of pattern, known as convergence, looks more like an accident of history than the divine scheme of a creator. It would be hard to argue that marsupials are better designed for living in Australia than are placentals. Marsupials tend to become extinct when they come in contact with their placental 'counterparts' (i.e. their ecological competitors). Marsupial Tasmanian wolves, for example, were driven to extinction in part because of competition with dingos - placental dogs introduced to Australia by the Aborigines.

Embryology

The phrase '**ontogeny** [development] recapitulates **phylogeny** [evolutionary history]' describes the idea, promoted by Ernst Haeckel, that 'higher' organisms such as humans reveal their evolutionary history by developing through the adult stages of 'lower' organisms such as fish. This idea is false and has been discredited, but it brings to mind certain aspects of development that are true. First, early-stage embryos across the vertebrate taxa (that is, animals with backbones) are practically indistinguishable. General features shared by all vertebrates, such as gill arches and spinal cords, develop first. Class-level characteristics develop from these generalized features; characteristics of the particular order then develop from these class-level features, and so on, until finally the characteristics of the species emerge. The embryonic structure that develops into the forelegs of lizards develops into the wings of birds and the arms of humans. In fish, gill arches become bony structures supporting the gills. In humans, one of the gill arches is converted into the lower jaw, another forms the eustachian tube between the ears and mouth, and others are reduced to tiny bones in our ears. Some structures, such as the tail, are lost completely. Human embryos never go through a stage that resembles an adult fish; instead, fish and human embryos start off with the same structures and then diverge from each other as they develop. These patterns of development are exactly what we would expect if fish, reptiles, birds and mammals all descended from a common ancestor and had subsequently been modified in different ways over time.

Vestigial structures and behaviours

Examples of vestigial structures and behaviours include: non-functional eyes on cave fish; wings on flightless birds (e.g. ostriches) and beetles; remnants of pelvic and hind limb bones in some snakes and whales; teeth in the embryos of toothless baleen whales; ear-wiggling muscles, wisdom teeth, tail bones and appendices in humans. Some excellent behavioural examples are provided by parthenogenic vertebrates. These are female-only species that reproduce asexually, i.e. the eggs develop without being fertilized by a male. Nevertheless, in some parthenogenic species, **reproduction** is enhanced by male courtship. In the Amazon molly (*Poecilia formosa*), courtship is performed by the unwitting males of a closely related sexual species. In the parthenogenic whiptail lizard *Cnemidophorus uniparens*, male-like courtship is provided by other females. The existence of vestigial structures and behaviours is very difficult to explain without invoking descent from an ancestor that made good use of them.

Normally unexpressed traits

Examples of normally unexpressed traits include: humans born with monkey tails; lizard scales produced by mouse skin when exposed to chicken tissue; rapid reversion of feral domesticated pigs to wildtype; fish teeth induced to develop in frogs (frogs ordinarily lack teeth). It takes a creative mind indeed to explain such phenomena without invoking evolutionary descent.

Jury-rigged adaptations and design flaws

Close examination of biological structures often reveals idiosyncrasies that suggest historical constraints. Evolution has no way of backing up and doing it over again the right way; it can only build on what it already has to work with. The vertebrate eye, for example, is superficially a wonderfully well-designed structure. It has been used over and over again as evidence that biological organs were designed by a creator the classic argument for design. In truth, however, the

P.234

vertebrate eye is wired backwards. Light needlessly passes through layers of cells in order to reach the photoreceptive pigments. The eyes of cephalopods (squid, octopuses, cuttlefish) are wired 'correctly' (convergently evolved).

The fossil record

For obvious reasons, fossils provide the hardest evidence for evolution. In Darwin's time, there were very few examples of clear intermediates, the missing links between major groups of organisms. Fossilization is an extremely rare event, so the fossil record will always be patchy, but no self-respecting palaeontologist would maintain that we lack intermediates today. For example, *Archaeopteryx* is a clear intermediate between reptiles and birds. This creature had bird-like feathers and wings, but it also had teeth instead of a beak, a long bony tail and claws on the leading edge of the wing. Modern birds do not have teeth, long bony tails or claws on their forelimbs these are reptilian traits. Equally clear fossil intermediates have been found between **reptiles** and mammals, between land mammals and whales, between **chimpanzees** and humans, and between many other living (and extinct) taxonomic groups.

Ample evidence for evolution was available by the early 1800s, but each piece of evidence had been gathered separately and interpreted in light of the prevailing theory (the Creation). Embryologists, for example, believed they were working out the divine developmental plan. The reason Darwin's book *On the Origin of Species* had such a tremendous impact was that he brought all of the evidence together and showed that it was far more consistent with a particular model of evolution (in which all organisms descended from one or a few common ancestors) than it was with special Creation (in which all species were created *de novo*). Darwin's greatest contribution - though it was not recognized immediately - was to provide a better mechanism for evolution than Lamarck did. That mechanism, of course, was natural selection (see also: **Selection**).

Biological evolution can be defined as: (i) any change in the characteristics of organisms over many generations (classic definition); or (ii) any change in the genetic constitution (gene frequencies) of a population of organisms over time (population genetic definition). The first version is closer to the common sense meaning of evolution, and is the definition used in practice by palaeontologists. The second definition is less restrictive. Anything that qualified under definition (i) would qualify under definition (ii), but not vice versa. Changes in the frequency of genes that have no effect on the phenotype are still considered to be evolution.

Artificial selection (see also: **Breeding**) produces a change in gene frequencies by separating the parents into two groups, selected and discarded, that differ in gene frequencies. Natural selection is subtler, and generally has much weaker effects; it merely favours genes that have positive effects on survival and reproduction. Over modest amounts of geological time, however, even relatively weak selection can have huge effects.

If certain basic conditions hold, evolution by natural selection is not only possible, it is inevitable. Those conditions are: (i) variation among individuals in heritable traits that affect survival or **reproduction**; (ii) variation is universal; (iii) most variable traits are at least somewhat heritable (offspring tend to resemble their parents); (iv) virtually all traits have some effect, however slight, on survival or reproduction. Thus, evolution by natural selection must be rampant.

The term microevolution refers to evolution within a single lineage. Macroevolution is the term used for speciation (the formation of new species) and the evolution of higher taxonomic groups.

Common misconceptions about evolution

1. Evolution is random. Natural selection, the primary driving mechanism of evolution, is anything but random - no more random than selective breeding.
2. Evolution occurs within individuals, or should somehow be directly observable. Evolution occurs between generations, not within individual animals. Major changes take millions of years.

3. Evolution violates the laws of thermodynamics. This is one of the most common and sophisticated-sounding arguments against evolution, because it seems to be based on the laws of physics. In fact, it is based on a misconception. The first law of thermodynamics basically states that you cannot get something from nothing. More formally, the total amount of energy in the universe is conserved - it never increases or decreases. This means, for example, that you cannot build a machine that produces more energy than it consumes. The second law states that, in a closed system, the net effect of energy transfer is towards increased entropy (disorder). Closed systems can never become more organized - overall, order always decreases. But evolution is an order-increasing process. Organized living systems have evolved from disorganized non-living matter, and simple organisms have evolved into more complex ones. Creationists have used this to argue that evolution is impossible, based on the second law of thermodynamics. But living organisms are not closed systems. The earth itself is an open system - energy pours in constantly from the sun. The only system that is truly closed is the universe itself. Order arises from disorder all the time. Complex trees grow from simple seeds. Snowflakes form from water vapour.

4. Natural selection is untestable. One Creationist argument goes like this: natural selection is untestable; to be scientific, a theory must be testable; therefore, natural selection is not a valid scientific theory. This sounds perfectly logical. The only problem is that the starting premise is false: natural selection is testable.

5. Evolution leads to progress. Modern evolutionists agree that evolution has no goal. Two hundred and fifty million years ago, there would have been no way to predict that mammals would evolve from reptiles. If it happened all over again, we can be certain of only one thing: the outcome would be quite different. Certain broad evolutionary trends, such as that towards increasing complexity or size, are undeniable. But this is only true on the average (e.g. virus evolution, mammalian size reduction over the last few million years). Given that life started from a single cell, there are few places to go but 'up'. Amoebas have just as long an evolutionary history as do humans. Bacteria are much more numerous and ecologically successful than insects; insects are much more numerous and ecologically successful than vertebrates. There is no justification for thinking that humans are somehow the most highly evolved organisms; we just have huge brains.

P.235

Processes other than selection that cause evolution

1. Genetic mutation. Mutations cause changes in gene frequencies, hence evolution. More importantly, mutation provides the raw material for natural selection.

2. Gene flow. Movement of individuals between populations can cause changes in population gene frequencies, hence evolution.

3. Genetic drift. Gene frequencies can change purely by chance (random sampling error), especially in small populations. Specific mechanisms include:

- Founder events. When a small population becomes isolated from a larger one (for example, by dispersing to an island), rare genetic variants (alleles) are likely to be lost and gene frequencies, in general, are likely to change.
- Random sampling during mating. Parents do not contribute all of their genes to each offspring, just a random half. This can result in chance variation in gene frequencies. Rare alleles, say the allele for purple eyes (if there was such a thing), are likely to get 'lost', i.e. disappear from the population, just by chance.
- Bottlenecks. A bottleneck is a population crash, followed by recovery - for example, because of overhunting, Northern elephant seals (*Mirounga angustirostris*) were reduced to 20 individuals by

1890, when hunting was banned. By 1993, the population had increased to about 30,000, but genetic variation remained extremely low. The Southern elephant seal (*Mirounga leonina*) went through a less severe bottleneck and shows correspondingly higher levels of genetic variability.

Evolutionary psychology

Evolutionary psychology is the study of the way in which a number of psychological traits or higher mental functions may have formed as either adaptations or functional productions of natural **selection**.

Evolutionary psychologists argue that many behaviour patterns, especially human behaviour patterns, have evolved to solve problems in past environments. Such adaptations may include the ability to acquire **language**, maternal and paternal **motivations**, and the ability to infer the emotions of others. Behaviours and **emotions** that are found worldwide in man are thought to be more likely to reflect evolved traits. These traits then interact with cultural or environmental stimuli to produce specific behaviours - for example, the specific language learned.

(LMD)

See also: Comparative psychology

Exaptation

Exaptation refers to the process whereby a (physical or psychological) characteristic acquires a function separate from that which led to its original development through natural **selection**. For example, **feathers** probably evolved as an adaptation of dermal structures to aid **thermoregulation**, and only after this did their use in flight become a possibility, and so the development of feathers for use in flight may be considered to have arisen as a result of exaptation. Exapted traits may therefore have features that appear to be redundant, since these features relate to their original function. However these apparently redundant traits can themselves have latent potential to provide the basis for new developments. Exaptation may also help to explain why some traits may be suboptimal or not fully functional. The development of **ritualization** and certain cognitive abilities can often be explained more accurately in terms of exaptation rather than adaptation. The term exaptation is preferable to the alternative 'preadaptation' that is often used, since the latter suggests that evolution is a teleological process.

Exotic companion animal

Exotic companion animals can include both indigenous and non-indigenous species, and both wild and captive-bred individuals. The principal distinction of exotic species used here is that they are non-domesticated species (see: **Domestication**). The range of exotic species kept as companion animals is vast. It includes invertebrates, such as spiders, scorpions, stick insects and mantises; and mammals, such as spiny mice (*Acomys sp.*), chipmunks (*Tamias spp.*), wallabies (*Macropus spp.*) and common marmosets (*Callithrix jacchus*), in addition to many birds, especially parrots and finches, **reptiles**, **amphibians** and the majority of tropical aquarium fish.

With the exception of tropical aquarium fish, reptiles and amphibians represent the majority of exotic companion animals. Reptiles are becoming increasingly desirable pets. As an indication of the popularity of exotic pets in 2007, it was estimated that 13.4 million reptiles were kept in 4.8 million households in the USA alone. A significant proportion of these are CITES (Convention on International Trade in Endangered Species)-listed, with 300,000 iguanas being legally imported into the USA in 2005. The vast majority of exotic animals for sale as companion animals are wild caught, and a number are endangered. Their trade is regulated by CITES. Additionally, national legislation often governs the import of wild-caught individuals of many species.

Within the UK the Department of the Environment, Transport and the Regions (DETR) is the primary body concerned with exotic pets. For example, it regulates trade in Mediterranean tortoises (spur-thighed, *Testudo graeca*, Herman's, *Testudo hermanni*, and marginated, *Testudo marginata*), and a DETR certificate is required to sell, buy, exchange or exhibit these species. In the UK, the keeping of large and/or potentially dangerous exotic species is also regulated under the Dangerous Wild Animals Act (1976).

As well as **conservation** issues, the exotic pet trade gives rise to serious **welfare** concerns. Many of the animals involved

P.236

are injured or die during their capture. **Mortality** rates vary by the type of animal, the country of origin, the techniques used during capture and **transport**, the species' ability to withstand the associated trauma and its ability to adapt to **captivity**. Mortality before export is typically high; for example, up to 50% of Senegalese finches and waxbills may die before leaving their country of origin. These mortality rates are commercially acceptable, as long as some individuals survive to the point of sale to the exporter, as wild capture costs very little for those involved.

The welfare of most exotic pets may also be compromised during shipment due to overcrowding, poor temperature control, **stress** and exposure to infection. Once in captivity, poor husbandry such as a lack of space, inappropriate temperature and/or feeding regimes and dietary deficiencies can result in a very poor prognosis, with an estimated 90% of pet reptiles dying within their first year in captivity. Poor welfare in reptiles and amphibians is a particular problem as it is far more difficult to detect than it is in mammals, for the simple reason that they lack the facial expressions and **vocalizations** that draw attention to their **pain** and **distress**. Consequently, many suffer in silence. Their **suffering** is also often

more prolonged than in mammals due to their slower metabolic rate, meaning that they take longer to heal or die.

Exotic companion animals present a number of challenges to owners, some of which are specific to exotics and some of which are more general. Providing suitably sized accommodation for large or active species such as primates, crocodilians, large lizards (monitors and iguanas) and snakes (pythons and boas) can be difficult. There may also be temperament considerations, as some can be aggressive - for example, male iguanas and some snakes. Perhaps the most universal challenge when keeping exotic pets is their nutrition. Many species require a specialized diet, not easily provided in captivity, such as live invertebrates (flies, crickets, etc.) or dead vertebrates (baby mice, rats, piglets, etc.). Furthermore, the nutritional requirements of many exotic species, not just of reptiles and amphibians, are not yet fully understood.

Malnutrition is often a key component of compromised welfare in exotic animals. It has been estimated that 15% of pet reptiles are malnourished. Critical factors include the quality and quantity of food and water, and in many reptiles the calcium:phosphorus ratio in their diet. The slow metabolism of reptiles also makes them particularly prone to obesity, which in turn is linked to fatty liver syndrome, arteriosclerosis and kidney calcification. The correct provision of water is just as essential as food, for inadequate drinking water or misting can cause gout and bladder stones (calculi).

In addition to food and water some reptiles have a requirement for ultra-violet B (UVB) radiation, as its action enables the synthesis of vitamin D, which is required for the adsorption of dietary calcium. An unbalanced calcium: phosphorus ratio leads to the development of potentially fatal metabolic bone disease (MBD). Animals suffering from MBD are susceptible to bone fractures. Although **bone strength** can be restored through the correct use of UVB, calcium supplements and a proper diet, skeletal deformities, such as curvature of the spine and a shortened jaw, will be permanent.

Many exotic pets have other special requirements. For example, particular care must be paid to temperature and humidity, and how these are provided. Ideally, the cage should have a temperature gradient to allow the animal to choose its preferred temperature, as incorrect temperatures can have serious metabolic consequences. In snakes and chelonians, if the temperature is too high, food may decompose before it can be digested; if it is too low, digestion is halted and food may begin to rot in the intestines. A correct humidity level is also critical in preventing a number of health problems, including respiratory and fungal infections and difficulties during sloughing. The substrate used in cages is also important. Some animals, such as chinchillas (*Chinchilla lanigera*), require a soiler sand-based substrate suitable for burrowing or **dust bathing**, while others may require water for swimming or bathing, or branches and ledges for climbing. However, not all substrates are suitable for all species; for example, sand can cause intestinal impaction in some species. Ticks and mites can also be picked up from contaminated substrate materials and these can harbour diseases and be a source of irritation.

Exotic species invasion

Exotic species (also called 'introduced', 'alien', 'non-native' or 'non-indigenous' species) are species that are not native to a particular habitat but have been accidentally or intentionally introduced there. If a species is able to colonize new areas beyond the initial site of introduction, and in the process to cause significant ecological or economic damage, then that species is considered 'invasive'. It is estimated that only about 1% of all species that are introduced to new habitats become problematic but, due to the increasing globalization of the world's economy, more and more species are being transported around the globe and the rate of invasion is increasing worldwide. The ecological impact of invasive species can be

profound, and is one of the biggest threats facing imperilled animal species, second only to habitat loss and degradation (**see also: Extinction**). The economic costs of invasive species are also increasing, and are estimated to be over US\$120 billion per year in the USA alone.

What makes one exotic species a successful invader while another fails to establish itself? There are two main reasons. First, the new habitat may lack the limiting factors that would keep the invading species' population in check. These limiting factors may be predators, **parasites** or competing species that are present in the invader's native habitat but missing in the new habitat. Without limiting factors, the population of the invading species increases and may overwhelm the native plants or animals in its new home. The second reason why some exotic species become successful invaders is that they possess behavioural traits that allow them to exploit the resources in their new habitat with remarkable efficiency. Invasive species are often generalists in terms of the food resources they can eat, and they may also possess a high level of **behavioural elasticity** that allows them to take advantage of other novel resources they encounter in their new habitat.

One of the most devastating examples of the impact of an invasive animal species is the ecological havoc wreaked on the island of Guam by the brown tree snake (*Boiga irregularis*). The brown tree snake is native to Australia, Indonesia, Papua New

P.237

Guinea and the Solomon Islands, and was accidentally introduced to Guam some time in the early 1950s.

By 1968 the snakes had dispersed throughout the 541 km² island and, by the 1990s, had reached peak densities of up to 100 snakes/ha. Brown tree snakes are generalist predators and will feed on lizards, birds and small mammals, as well as bird and **reptile** eggs. It wasn't until 30 years after the initial introduction that researchers realized this snake was largely responsible for the mysterious decline of many native species. The brown tree snake has caused the local extinction of nine of the island's 13 native forest-dwelling bird species (including the global extinction of the Guam flycatcher, *Myiagra freycineti*), as well as over half of the native lizard and bat species. The native species are unable to protect themselves against this exotic predator, and today only isolated pockets of native populations remain.

Part of the reason that researchers did not make the connection between the disappearance of the birds and the presence of the exotic snake was behavioural; brown tree snakes are arboreal and **nocturnal**, so they are hidden during the day and extremely hard to locate at night. The impact of the brown tree snake on Guam also includes significant economic damages, as these climbing snakes will often shortcircuit power lines, causing many power outages. Local poultry businesses have also been devastated by the loss of eggs to the predatory snake. Efforts to control the brown tree snake are ongoing, as are efforts to prevent the transport of the snake to new, vulnerable habitats.

The role of behaviour in determining whether an animal becomes a successful invader is well documented. It is also essential, however, to understand the role of behaviour in native species' ability to respond to invasive animals and plants. Invasive species can impact native species directly through **predation** or competition, but also indirectly by altering the ecosystem upon which native species depend. Often these changes occur very rapidly, and native species may not have time to evolve adaptations to the new conditions. On the other hand, if native species possess enough behavioural elasticity, they may be afforded more time to adjust to the changes that are occurring - but their evolutionary trajectory will be forever altered.

In some cases native animals may, to their detriment, seek out an invasive species if they mistakenly see the invader as a resource. For example, females of several native *Pieris* butterfly species will lay their eggs on invasive plants (e.g. *Thlaspi arvense* and *Allaria petiolata*) that are toxic or even lethal to their caterpillar offspring. There is some evidence that these females may prefer to lay their eggs on the invasive plant rather than on a more appropriate native plant. In that case, the invasive plant becomes an

'ecological trap' because the normal cues the females use to find egg-laying sites are now maladaptive and lead to reduced survival of their offspring.

In other cases, however, the native species may learn and/or evolve behaviour that helps them to compensate for the presence of an invader. For example, red-legged frog tadpoles (*Rana aurora*) from areas that have been invaded by an exotic predatory bullfrog (*Rana catesbeiana*) will reduce their activity and hide when they detect chemical cues from the bullfrog. Tadpoles from other areas that have not been invaded by bullfrogs do not show any change in behaviour when presented with the same chemical cues. Whether the anti-predator behaviour in tadpoles that live in areas with bullfrogs is learned or has evolved over several generations is unclear. In either case, the change in behaviour is crucial to the survival of these frogs, as it is very difficult and expensive to control established bullfrog populations.

Controlling any invasive species is difficult and expensive, and may even be impossible if an invasion has gone undetected for a long period of time. The survival of native species may depend on whether, in the short term, they are able to adjust their behaviour to compensate for the presence of the invasive species and whether, in the long term, they can evolve adaptations that allow them to coexist with the exotic invader.

Experimental analysis of behaviour

The experimental analysis of behaviour is a scientific discipline that arose from the philosophy of **behaviourism**. Behaviourism is a natural science approach to **psychology** that emphasizes the study of environmental influences on observable behaviour. The philosophy is associated with John B. Watson, an American psychologist who advocated that psychologists define psychology as the study of observable behaviour rather than as the study of the **mind** or **consciousness**. The behaviourist movement was meant to counter Sigmund Freud's psychoanalysis, in which the unconscious mind was believed to play a large

role in human behaviour. By avoiding the terms consciousness and mind and focusing on observable behaviour, psychologists could not only study human behaviour scientifically, but they could also study animal behaviour and compare it to human behaviour.

The behaviourist movement was popularized by **B.F. Skinner**, an influential psychologist who developed a theory of operant conditioning to explain how much behaviour developed. Skinner believed that the processes of learning and natural selection are very similar to each other. Whereas Skinner acknowledged that heredity may play a role in behaviour, he also believed that much of our behaviour and that of other animals results from having learned what will happen after we perform the behaviour. For example, behaviours that lead to favourable outcomes are more likely to be repeated and increase in the future. These favourable outcomes are often referred to as reinforcers. Behaviours that lead to poor outcomes are less likely to be repeated and

P.238

decrease in the future. Poor outcomes are often referred to as punishers.

Behaviours that are influenced by their consequences are known as operant behaviours. Therefore, **operant conditioning** is a type of learning in which the future probability of a behaviour is affected by its consequences. Operant behaviour is more voluntary and flexible than stimulus-elicited or reflexive behaviour. Viewing human and animal behaviour in this way implies that behaviour can be influenced by controlling the environmental consequences for a particular behaviour or class of behaviours.

Principles derived from studies conducted in the field of the experimental analysis of behaviour have been very influential in guiding animal management and husbandry in laboratories and zoos. For example, the principles of operant conditioning have been incorporated into animal training programmes in which positive **reinforcement** (rewarding stimulus) is provided after a particular response to increase the likelihood that the response will occur again. In this way, new behaviours or patterns of behaviour can be shaped over time and the frequency of desirable behaviours can be increased.

Common reinforcement provided in captivity includes food, the opportunity to engage in social activity and manipulable non-food items designed to sustain interest and activity levels. Operant conditioning can also be used to decrease abnormal or stereotypic behaviours that can appear in captive animals, presumably as an artefact of the captive environment. The frequency of unwanted behaviour can be decreased by either punishing the behaviour or by removing the reinforcement that is sustaining the behaviour. Punishment involves the weakening of a behaviour through either application of an aversive stimulus (positive punishment) or the removal of a reinforcing stimulus.

From an animal welfare point of view, **punishment** is not the method of choice for deterring behaviour. Early experiments by Skinner and others led them to conclude that punishment was not a very effective method for controlling behaviour, and that it often had only temporary effects at best. Research has shown that there are risks associated with punishment if it is not provided correctly. First, punishment does nothing to increase appropriate behaviour - it only decreases the unwanted behaviour. Secondly, punishment can lead to escape and **avoidance behaviour**. Animals in zoos and laboratories will often hide or escape from the source of punishment. Thirdly, punishment can sometimes lead to either an aggressive response or a strong emotional response. Finally, punishment can be physically or mentally harmful if not applied appropriately, leading to high levels of stress. Discovering and eliminating the reinforcement for a behaviour, combined with positive reinforcement for desirable behaviour, is generally a preferred means of eliminating unwanted behaviour as opposed to punishment, when considering the welfare impact of the processes involved.

In conclusion, the experimental analysis of behaviour provides a framework for systematically and scientifically evaluating the variables that contribute to the presence or absence of behaviour, patterns of behaviour, frequency of behaviour and strength of behaviour. Because of this, it is a powerful field for understanding animals and their interactions with the environment. Most importantly, the experimental

analysis of behaviour has led to more humane and effective techniques for managing the behaviour of captive animals. Specifically, the principles of operant conditioning can be used to increase the quality of captive environments, improving both the physiological and psychological well-being of animals in captivity.

Experimental playback

Experimental playback allows auditory **communication** to be experimentally manipulated. Essentially, animal **vocalizations** are recorded and then played back through loudspeakers and the response of the receiver(s) monitored in order to identify the function of the vocalization. For example, vervet monkeys (*Cercopithecus aethiops*) are known to give different alarm calls in response to different predators: a loud barking alarm is given in response to leopards, a short double-syllable cough signals the presence of an aerial predator (eagle), while a 'chutter' call is given in response to the presence of a snake. That the monkeys responded differently to the different alarm calls can be demonstrated by playing back the calls through loudspeakers: when the bark was played, vervet monkeys ran to and climbed nearby trees, the double-syllable cough caused the monkeys to look up and run to the nearest bush and the 'chutter' resulted in vervets standing on their hind legs while scanning the surrounding grass.

Experimental playback allows the observer control over potentially confounding variables. For example, cuckoo chicks elicit a higher parental feeding rate than the host bird's own chicks. This could be due to the greater mouth gape of the cuckoo chick, but it could also be due to the different begging call of the cuckoo chick. By playing back a cuckoo chick begging call at the nest when no cuckoo chick was present, it was revealed that the call alone was capable of stimulating parent birds to bring more food back to the nest. Experimental playback can also reveal costs of chick begging: eggs in artificial tree swallow nests were more likely to be predated when the taped sounds of begging chicks were played nearby.

(PE)

Exploratory behaviour

It is difficult to define exactly what is meant by exploratory behaviour; indeed, one of the early researchers on this topic sadly observed that it consisted of a large range of behavioural acts that 'have nothing very tangible to hold them together apart from our failure to recognize a specific biological function that can be associated with them'. Nevertheless, it was quickly recognized that exploratory behaviour is an important subject because a large part of an animal's behaviour is characterized not so much by activities that obviously serve its biological needs but rather by pronounced tendencies to explore, investigate and seek out new forms of stimulation. In its broadest sense exploratory behaviour refers to all activities concerned with gathering information about the environment.

P.239

Types of exploratory behaviour

During the early period of research into exploratory behaviour a number of important distinctions between different types of exploration were made. One such distinction is between *extrinsic* exploration, which has a clear goal - namely to gather information about a conventional reinforcer (e.g. a hungry animal searching for food), and *intrinsic* exploration, which has no such goal in that it is directed at stimuli of little obvious biological consequence. From an **adaptive** viewpoint it is doubtful whether this distinction has much validity, because changes in the animal's environment not related to conventional reinforcers may still potentially have repercussions for survival and hence should be investigated. Nevertheless, the extrinsic/intrinsic distinction has been important in the development of motivational theory. While the motivation for extrinsic exploration can at least partly be explained on the basis of the reinforcement obtained as a result of the information gathered, explaining the motivation for intrinsic exploration is far more difficult, as here the stimuli involved appear to be rewarding in themselves.

Another distinction is between *specific* exploration, defined as gathering information about a specific event or object, and *diversive* exploration, which is the gathering of information from any source. For example, the former is the type of behaviour we perform when we are 'looking for' something in particular, while the latter is encompassed by such terms as 'recreation' and 'entertainment'. Specific and diversive exploration are thought to be caused by different motivational states - specific exploration being linked to 'curiosity' about a particular stimulus change, and diversive exploration to '**boredom**' created by a general lack of **stimulus** change.

The final major distinction is between *inspective* exploration (also called *forced* exploration) - which is responding to stimulus change - and *inquisitive* exploration (also called *free* exploration) - which is responding for stimulus change. Inspective exploration involves the animal adjusting to new stimuli that are forced upon it, as, for example, when a rat is placed into a novel maze. In contrast, inquisitive exploration involves the animal freely seeking stimulus change, as, for example, when a rat learns to bar press solely for exposure to novel stimuli. The adaptive significance of responding to a change in the environment is clear, but there has been much debate on why animals should also actively seek change.

Determinants of exploratory behaviour

The strength and direction of exploratory behaviour are determined by a large number of factors, but experimental studies have revealed a number of stimulus characteristics that stand out as being the most influential. These include properties such as novelty, surprisingness, ambiguity, incongruity and complexity. The term 'collative variables', i.e. variables brought together for comparison, was coined to cover these characteristics because, apart from complexity, they are properties of an animal-environment interaction rather than of the environment itself. The collative variables imply an expectancy by, and induce uncertainty in, the animal.

Methods used to study exploratory behaviour

Research on exploratory behaviour usually involves exposing the animal to environmental stimuli that it has either never before experienced or not experienced for some time - conventionally termed the novel stimuli or novel environment. Many experiments on inspective exploration have involved briefly putting an animal into a relatively homogeneous novel environment, such as a maze or open field, that is devoid of food, water, objects and other animals, and from which it cannot escape. In such studies the degree of movement shown (e.g. by marking out the floor of the open field in squares and counting the number crossed) is often taken as a measure of 'locomotive exploration'. There are, however, several problems with this interpretation; for example, locomotory scores are very likely to be contaminated by changes in activity levels and attempts to escape from the apparatus. Furthermore, the usefulness of this general approach is questionable because in the wild it will be very rare that an animal suddenly finds itself in a novel environment from which it cannot escape.

Experimental protocols that more closely resemble the conditions under which animals encounter novelty in the wild involve either: (i) exposing the animal to a number of discrete novel stimuli within a familiar area; or (ii) allowing it to move freely between a familiar area and a novel environment. In these tests, measures such as the number and duration of contacts with the various novel objects, and the latency to enter and time spent in the novel environment are used as indices of exploration. In many studies the novel stimuli do not impinge upon the animal until after it has made a specific response. Thus the resulting behaviour is inquisitive exploration because the animal responds for, rather than to, the environmental change. Typically the animal is placed in a Skinner box and an environmental change, such as a brief exposure to a novel visual stimulus, is made contingent on a lever press or similar operant. Experiments of this kind have shown that response-contingent novelty acts in much the same way as a conventional reinforcer like food or water and produces learning - i.e. a relatively permanent rather than a temporary change in behaviour.

Some studies have manipulated the dimension of stimulus complexity to see how an animal's response depends not just on the **novelty** of an environmental change but also upon the nature of that change. In such experiments stimulus complexity is manipulated by varying the number of distinguishable elements within the stimulus and the degree of difference between them. There is good evidence that complex stimuli are preferred in **choice tests**, elicit more exploration and make stronger sensory reinforcers than simple ones. However, there is also evidence that highly complex stimuli are actively avoided and, as discussed below, this finding has important theoretical implications.

Theories of exploratory behaviour

For the most part theories of exploratory behaviour have failed to take account of the adaptive significance of exploration and, instead, have concentrated upon its immediate proximate causes. Initially, exploration was thought to be a secondary or acquired **drive** serving one or other of the classic drives, e.g. searching for food. However, the results of latent learning experiments have shown that animals would explore and learn about their environment even when their primary **needs** had been satiated. A secondary drive status for exploration was therefore dropped. Instead, it was proposed that this behaviour

P.240

had its own drive because deprivation and satiation effects were found within exploratory behaviour similar to those found within classic need states. For example, lengthening the interval between exposures of novel stimuli increased exploratory behaviour and it was also found that exploration decreased within the session following such an interval.

Two main modifications of **drive theory** were proposed. One argued that novel stimuli motivated exploration, i.e. a curiosity drive, while the other proposed that it was the lack of novelty that energized this behaviour, i.e. a boredom drive. Unfortunately, these explanations were in large part circular because, unlike the other primary drives, there were no independent physiological correlates for curiosity and boredom, and so these drives were both inferred from and used to explain exploratory behaviour (e.g. an animal was said to be bored only because it subsequently explored).

Difficulties arose with both formulations. It was hard to explain inquisitive exploration using the concept of a curiosity drive because here the animal is seeking novel stimuli and yet a curiosity drive is not present until after the animal has come into contact with such stimuli. While a curiosity drive could theoretically explain inspective exploration, because novel stimuli are already present to both elicit and then reduce the curiosity drive, it could not predict the empirical fact that animals would avoid 'very' novel stimuli. The boredom concept could account for inquisitive exploration as an attempt to reduce boredom by a self-produced exposure to new stimuli. Furthermore, it could also account for the direction of inspective exploration in that the most novel object is the one least resembling the boring situation and thereby the most favourable. However, like the curiosity concept, it had difficulty in explaining why

extreme novelty should be aversive. In addition, boredom theory predicted that the longer the period an animal spent in a monotonous environment the greater would be its urge to explore, and this was found not to be the case. Under prolonged sensory restriction exploratory behaviour declined and was replaced by a preference for little or no change in environmental stimulation.

Since explanations of exploratory behaviour using either curiosity or boredom concepts alone were not successful, the remaining attempts to use drive theory involved both components. It was argued that all incoming sensory stimulation contribute to a general drive, or **arousal** level, and that for a given task there was an optimal level of arousal that the animal strived to maintain. Theories differed about the form of the relationship between sensory input and arousal, but all concluded that there is an optimal level of sensory input that the animal prefers to maintain. Thus, if the level of environmental stimulation falls below the optimum the animal will seek novelty, while if it rises above the optimum the animal will strive to withdraw from that environment. Unfortunately there was no generally accepted mechanism whereby the arousal state of an animal could be measured, let alone its discrepancy from a vaguely defined optimal level. In addition it was proposed that arousal was determined not just by the novelty of a stimulus but also by such factors as its intensity and meaning and by internal stimuli of the animal associated with primary drive states. As one researcher remarked, the arousal concept provided 'the basis for explaining everything and predicting nothing' and, as a result, it had relatively little impact on animal studies.

Some theories of exploratory behaviour have recognized its adaptive significance. The ability to adapt to unfamiliar and novel situations is a fundamental requirement for animals living in complex and stochastic environments, and this must involve a comparator process in which the current stimuli are compared to past experience. '**Cognitive model**' theories of exploratory behaviour argue that the animal builds up a neuronal representation of spatial and/or temporal relationships within its environment (i.e. a cognitive model) that it then uses to find its way around and to anticipate events. Neurophysiological studies have implicated the hippocampus in such a function. The advantage of having a model of your environment is indicated by experiments showing that familiarity with the locality greatly improves, for example, an animal's ability to escape predators. The goal of exploratory behaviour was thought to be the elimination of any discrepancy between incoming stimuli and the stimuli predicted by the cognitive model. It was proposed that the size of the discrepancy determined the form of exploratory behaviour: a small discrepancy triggered inspective exploration, while a large discrepancy resulted in withdrawal from the novel stimuli. However, it was difficult to account for inquisitive exploration on this basis because inquisitive exploration necessarily involves moving away from familiar stimuli towards novel ones that cause larger discrepancies.

The concept of a cognitive model is also a central plank of the more recent 'information primacy' theory of exploratory behaviour. Here, the term information refers to the reduction of uncertainty: thus when an animal explores a novel environment it reduces its uncertainty about the stimuli experienced and gains information, but when it moves through a completely familiar environment there is no uncertainty to be reduced and no information is gained. It is argued that information-gathering behaviour is continuously present, forming a substratum upon which other, more obviously goal-directed, behaviours occur. We have therefore moved from a position where exploration simply served the reduction of primary needs to one in which uncertainty reduction is given pride of place and need states have to be sufficiently intense to be able to break into and direct the information-gathering behaviour.

The proposal that animals have an inbuilt tendency to continually reduce environmental uncertainties is supported by neurophysiological studies of the extended lateral hypothalamic corridor. This is thought to form a 'seeking system' that: (i) spontaneously learns about uncertain environmental events that may predict resources; (ii) translates correlations between such events into perceptions of causality; and (iii)

seeks information to confirm predictions about causality. Electrical stimulation in this brain area triggers very vigorous exploratory behaviour in animals, and in humans gives rise to feelings of 'intense interest'.

One prediction from the information primacy theory is that if an animal is given the choice between feeding most efficiently in a familiar situation or less efficiently on the same food in an unfamiliar situation it will choose the latter, but that this preference will decline with increasing hunger. Empirical support for this prediction comes from **contra-free loading** experiments in which animals are given the choice between

P.241

feeding freely from a dish of food or working (e.g. searching, solving puzzles, bar pressing) for the same food. When no uncertainty is associated with either food source the animals prefer to eat freely from the most profitable source, i.e. the dish. However, if uncertainty is associated with the food for which they have to work (e.g. it is camouflaged), they choose this less profitable food source rather than the dish, and this preference decreases with increasing hunger. One reason why it has generally been reported that animals forage where it is easiest to obtain the largest amount of food may be because the experimental protocols commonly used in optimal foraging experiments permit only the minimal expression of information-gathering behaviour. The subjects are deprived to a degree that ensures near maximum foraging efficiency, and the short trials are terminated before the animals have begun to vary their behaviour as a result of satiation.

Information primacy theory argues that animals do not have an optimal level of environmental stimulation that they strive to maintain, as proposed by arousal theories, but rather an optimal rate at which discrepant sensory input is processed, i.e. a preferred rate of information processing. Experiments on human attention indicate there are capacity limitations on the amount of such processing that may be conducted at any given time, and the information primacy theory proposes that the processing capacity currently available determines the preferred level of stimulus change. When this capacity is inadequate for the efficient processing of the uncertain stimuli anxiety accrues and the animal leaves the possibly dangerous situation. Thus inspective exploration is explained on the basis of the need to reduce the uncertainty associated with the novel stimuli present, and the avoidance of very novel stimuli by there being insufficient capacity to process the discrepant inputs. When the capacity is greater than that required, another negative state, boredom, occurs. Boredom ensures that the available processing capacity is effectively used to improve the reliability of the cognitive model by triggering inquisitive behaviour to seek, and then gather information about, unfamiliar and novel stimuli. A positive affective state exists when the level of environmental change approximates the capacity available to process the discrepant stimuli.

The previous levels of discrepant sensory input experienced in the environment are thought to determine the available processing capacity - i.e. capacity increases with time spent in a complex and stochastically varying environment and decreases in a constant simple environment. A prolonged period under sensorily restricted conditions does not, therefore, lead to a high level of exploratory behaviour, because the lack of discrepant input in that environment has resulted in a greatly reduced capacity to process novel stimuli. Thus the **welfare** of animals kept under such conditions is compromised because the processing capacity becomes so small that any environmental changes create high levels of anxiety and **stress**.

Extinction

The term extinction is used in several ways in biology, referring to the elimination of a species or a behavioural response in certain circumstances.

The high rate of extinction of species in geologically recent times (the last 100,000 years) has been linked to man's spread and activity, although the evolutionary record points to mass extinctions occurring periodically throughout life's evolutionary history. The current rate of extinction appears to be the highest it has been since the end of the Mesozoic era about 65 million years ago, when the Earth was subject to a number of natural catastrophes including major volcanic eruptions and meteorite impacts. Within **conservation**, the term extinction may be used to refer to the elimination of animals within a given geographic region, rather than to the Earth as a whole. The term 'extinct in the wild' is used by the International Union for Conservation of Nature and Natural Resources (IUCN) to refer to species that are only maintained in captivity, some of which it may not be possible to reintroduce due to the loss of natural habitat.

Extinction can also refer to the disappearance of a conditioned behavioural response to a conditioned stimulus (see: **Conditioning - types of**) as a result of elimination of its **reinforcement**. Extinction can be successfully employed as a behaviour modification technique (e.g. to stop a dog jumping up for attention), but often the behaviour will intensify before it starts to decline, as part of a phenomenon known as an 'extinction burst' due to frustration of the conditioned response. The range of conditioned behaviours treatable in this way is therefore practically quite limited.

(KT)

Eye white responses

Emotional experiences, at a basic level, enable animals to react to and interact with the surrounding environment. The amount of eye white (or sclera) shown by an animal is considered to be closely linked to its current emotional status. More eye white is visible when the upper eyelid is raised, and this is thought to be orchestrated by the **sympathetic nervous system**. In general, negative **emotions** such as **fear**, **frustration** and surprise (i.e. response to unpredictability) cause the eye to widen, revealing a greater proportion of the sclera. In contrast, less eye white is visible when animals are in a more positive emotional state, performing behaviours such as **grooming** and resting.

The benefits to the animal showing increased sclera are not completely understood, but it does communicate clearly to other animals that a heightened awareness of the environment is required. This response is deemed to be innate in most animals, and learned and automated very early on in human emotional development. The brain of the observer responds to increased sclera before any conscious awareness takes place, preparing the observer for prompt evasive action. The amygdala of the **brain** is involved with the reflex response of an observer, and humans who have sustained damage to the amygdala have difficulty in recognizing a fearful expression or

P.242

are unable to detect differences between the gradients of fearfulness. In studies on animals, cattle that were either startled or thwarted from performing a desirable behaviour and cows separated from their calves all showed a significant increase in the proportion of visible eye white.

The increase in visible sclera under negative emotional conditions and the decrease under positive emotional states indicates that the eye white response may be a useful and reliable indicator for the assessment of welfare.

Facial perception and recognition

Faces are probably the most important visual stimuli in the social environment of visually dominant species, such as humans. They not only provide visual information about an individual's gender, age and familiarity, but also convey significant cues to affective state (e.g. anger, happiness), cognitive activity (e.g. concentration, **boredom**), **temperament** and **personality** (e.g. hostility, shyness). It is not surprising that the ability to recognize these cues and to respond appropriately plays an important role in the social life of higher primates - and possibly of other species as well.

Humans have extraordinary sensitivity and capability for detecting, remembering and recognizing faces. Soon after birth, infants show a preferential response to faces. Our ability to process facial information develops quickly through an experience-dependent process of gradual specialization that gives us a marked advantage in recognizing **conspecific** (or even own race) faces. Adults can differentiate the expression and identity of briefly and peripherally presented faces even when focal attention is not fully available (Grossmann and Johnson, 2007). It has been further argued that face perception and **recognition** (at least in humans) involves a face-specific cognitive and neural mechanism based on empirical findings such as:

1. Face and non-face object processing depends on different **brain** areas. A few distinct neuroanatomical regions in the cerebral cortex (i.e. fusiform gyrus) have been predominantly associated with face processing.
2. Face and non-face object processing can each function independently without the other. The selective impairments of face and object recognition (prosopagnosia and visual agnosia, respectively) have been observed in neurological patients.
3. Face and non-face object recognition process information differently. Whereas reliable object recognition can depend on individual parts (featural processing), face recognition is more holistic and relies heavily on the overall configuration in faces (configural processing). The hallmark commonly used to differentiate these two processes is the face inversion effect, in which detrimental recognition performance is more evident for inverted faces than for inverted non-face objects.

The critical role of faces in social communication is not restricted just to humans. In the **phylogeny** of primates, there is an increasing trend towards larger and more complex **social groups** in which individuals rely more on facial signals for **communication**. Like humans, non-human primates (e.g. chimpanzees and rhesus monkeys) can display, perceive and respond to sophisticated facial expressions, a crucial component for successful interpersonal relations. They are also able to perceive differences between individuals of their own species based on facial cues alone. For instance, monkeys at an early age can respond appropriately to the expressions of other individuals and recognize their faces. They can even discriminate the faces of unfamiliar individuals after only a short exposure to sets of their images. While inspecting faces, they exhibit a similar eye-scanning pattern to that of humans, allocating a disproportionate share of fixations to facial regions that provide diagnostic information for face processing

(e.g. eyes for detecting identity and gaze direction). Once the faces are turned upside down, they also suffer from the face inversion effect, at least towards conspecific faces. Studies such as these provide compelling evidence that non-human primates can perceive facial identity and facial expression based on purely visual cues, even when presented as two-dimensional black-and-white face images.

The sensitivity of detecting facial signals and the capacity for differentiating individuals based on faces are spread beyond primates. With experimental protocols such as match-to-sample or visual paired comparison tasks, many behaviour studies have observed that mammals such as cattle, sheep, pandas, dogs, birds such as budgerigars, and insects such as wasps and bees are able to detect various facial cues and recognize **conspecific** faces based on visual cues alone.

For some species, their remarkable facial perception and recognition capability may be extended beyond faces of their own species. The faces of other species they can process, however, are subject to the animal's exposure and differential experience towards these species and their behavioural significance. For instance, some captive non-human primates (i.e. chimpanzees and monkeys) can respond to human facial cues such as gaze direction, discriminate individual human faces and demonstrate the human face inversion effect. Domestic dogs also exhibit this phenomenon, despite their greater genetic distance from humans compared with that from other primates. It has been argued that the ability to extract information from human faces and respond appropriately may have had a selective advantage during the process of **domestication**. Consequently, domestic dogs may have evolved some human-like strategies for face processing. This hypothesis has been supported by empirical observations, such as the finding that domestic dogs can use internal representation of their owner's face to correlate facial and vocal signals; they can use faces to differentiate human individuals, and their sensitivity to human directional communicative cues exceeds that of non-human primates in certain tasks, such as following human gaze direction to find hidden food (see Hare and Tomasello, 2005).

Overall, sensitivity to faces can be found in many species. This sensitivity seems to be inherited or developed at an early age, and could be shaped by the animal's experience according to its adaptive behavioural significance. It is unclear, however,

P.244

whether a similar cognitive or neural mechanism in face processing is shared by these diverse species.

FAP/FMP (Fixed action pattern/Fixed motor pattern)

Fixed action patterns (FAPs) are unlearned (**innate**), repetitive movements produced by a neural network known as the **innate releasing mechanism (IRM)** in response to external stimuli (sign stimuli/releasing stimuli) that are relatively unaffected by **feedback** from the stimuli and are species-specific. Their relative lack of dependence on environmental feedback means that such behaviours, which often relate directly to survival or **fitness**, can be performed effectively the first time the animal attempts them. Some well-known examples of FAPs include egg retrieval in the greylag goose, **courtship** displays in male sticklebacks and **grooming** sequences in mice.

The term 'fixed action pattern' has been criticized for its implied rigidity of behaviour patterns, leaving little room for individual variation or even variation in different bouts of the behaviour. While some behaviour patterns do have this quality, others show more variability in their performance, and thus the term **modal action pattern (MAP)** was devised to account for less rigid but still predictable behaviour patterns.

Many consummatory behaviour patterns can also be classified as FAPs, such as eating, drinking or copulatory behaviour. When an animal has **motivation** to perform a behaviour pattern, levels of **appetitive behaviour** are increased to attempt to achieve the consummatory behaviour. However, with the **intensification of animal production**, a number of consummatory behaviours are not possible or their performance is restricted. Thus, it has been theorized that some forms of **stereotypies** derive from the inability to perform these FAPs and satisfy their underlying motivations.

Farm Animal Welfare Council

The Farm Animal Welfare Council (FAWC), created by an Act of Parliament in the UK in 1979, is an independent committee that gives advice to the government and produces reports available for the public, including the agriculture industry. Its terms of reference are to keep under review the **welfare** of farm animals on agricultural land, at market, in transit and at the place of **slaughter**, and to advise the government of any legislative or other changes that may be necessary. FAWC statements on attitudes and practicable welfare policy have had influence in many countries.

Farm assurance scheme

How does the scheme work?

Quality assurance can be provided for any product that has been certified to meet defined standards. The term 'farm assurance' may be applied to the quality assurance of most farm products, but in this article will refer specifically to the assurance of products with a farm animal origin, from the birth of the animals, through rearing and **transport**, up until the point of **slaughter**.

Farm assurance provides guarantees for consumers on a range of areas such as food safety, product traceability, environmental impact and animal **welfare**. This is provided through possession of a defined set of standards, owned by a farm assurance scheme, which are formally checked (audited) on a farm by a farm assurance assessor, who is, ideally, independent of the scheme. The various schemes may assure to the minimum level of legislation compliance or have standards that go far beyond this. Schemes may also have different ethical emphases: for example, organic standards provide specific assurances about environmental issues and, in the UK, the **RSPCA's Freedom Food Scheme** has an animal welfare focus.

Assurance schemes for farms were developed from the 1980s onwards as a voluntary private-industry initiative to differentiate members' products within the marketplace. As retailers have come under increasing pressure to demonstrate food safety through traceability, and subsequently other forms of product provenance such as animal welfare, farm assurance has grown.

The first critical component of a useful farm assurance scheme is a set of meaningful, well-defined standards with which auditors are able to assess members' compliance. Animal welfare standards have typically been based upon some of the 'inputs' that affect an animal's welfare, such as the housing, feed and **stocking density**; however, other inputs such as

P.245

genetic make-up and **stockperson** ability have been less easy when defining standards. In order to better evaluate the effect of these inputs on the welfare of farm assured animals there have been recommendations from organizations, including the Farm Animal Welfare Council (**FAWC**) and Compassion in World Farming, to include some 'outcome' measures of animal welfare (direct assessments of animal welfare; **see also: Welfare measurement**) such as physical **health** and behaviour. This is being

investigated by a number of farm assurance schemes and, in a separate initiative, the European Union (EU) has funded a large pan-European project to develop welfare outcome measures for cattle, pigs and poultry, termed 'Welfare Quality'.

There has been little research directly considering whether belonging to a farm assurance scheme results in an overall improvement in animal welfare; many farm assurance schemes aim to be almost universally available to farmers by setting welfare standards at, or marginally above, the legal minima with which they must, in any case, comply, and are therefore not likely to produce significantly improved welfare. One study to evaluate the effect of belonging to a high-welfare, but inputbased, farm assurance scheme on the welfare of dairy cows showed an equivocal effect, with some welfare outcome measures, such as **mastitis**, being better on the assured farms whereas others, such as **lameness**, were worse. However, a review of the welfare of animals on organic farms concluded that, as long as animal health can be maintained, **organic farming** systems are in a better position to provide good animal welfare compared with conventional systems. With the increasing use by farm assurance schemes of appropriate standards relating to animal welfare to accurately assess and monitor improvements in animal welfare, there will come the potential to improve animal welfare over time for members.

The second critical component of a useful farm assurance scheme is accurate auditing of welfare standards by farm assurance assessors. A thorough routine inspection may be able to identify farms that comply with standards on any given inspection day, but a better approach is to provide assurance that there are systems in place on a farm to ensure continuing compliance with the standards beyond the inspection day. Whether welfare inputs or outcomes are being assessed, there are several important auditing considerations. The assessors must be standardized in the interpretation of, and judgement of compliance with, the standards. This process should be ongoing beyond the initial training, for example by having multiple assessors at an assessment, or assessing photographic/video footage of a farm. The timing of the assessment and the interval between assessments need to be considered, and may vary depending on species. For example, to understand the range of conditions on a farm and welfare the animals may experience, it may be useful to visit a farm at various parts of its cycle. For a beef farm this might be at different times of the year, but for a broiler chicken unit this would be over the rearing period of a few weeks. If benchmarking is desirable then all farms would need to be visited at a comparable time.

Who wants farm assurance?

Farm assurance may be desirable or required by some or all parts of the food market, from processors to retailers and consumers. For processors and retailers farm assurance can provide evidence, when required, of due diligence in ensuring that appropriate product standards, particularly relating to food safety, have been met. The decision about whether and how to pass this information on to the general consumer depends upon the market advantage of doing so. There may be no visible evidence to a consumer, but information is available on request or general claims may be made, such as 'all our meat is farm assured'. More specifically, farm assurance logos may accompany products and, at times, this may be accompanied by more detailed information such as 'from sheep that graze grass all year round'. In many countries the market has responded to an increasing desire by consumers for knowledge of the welfare provenance of animal products, and consequently for higher-welfare products themselves.

The World Trade Organization (WTO) does not currently allow trade restrictions on products solely on the basis of animal welfare (see also: **International regulation of animal welfare**). If the desire by consumers for welfare-differentiated products continues to increase, it may be that the WTO accepts that appropriately certified minimum welfare standards could be a condition attached to international trade to benefit consumers rather than to protect producers. An alternative scenario if the current WTO rules continue is that higher-welfare products are denied the opportunity to differentiate themselves on the global market, thus reducing the incentive for their production. Some international trade in farm assured products exists at present, where a specific customer requires compliance with farm assurance standards.

For example, large EU retailers buying chicken from Thailand or Brazil may insist upon compliance with equivalent farm assurance standards by their national suppliers.

Farmed animals

Farmed animals are those animals whose production is used to benefit humans who, in return, claim ownership, provide protection, decide on matings and take responsibility for food supply. A spectrum exists of human-animal relationships of the farming kind. Animals that are kept in confinement or enclosure throughout their lives and whose reproduction is controlled are very obviously farmed. Examples are familiar farm livestock species, bees and silkworms. Animals that are free ranging and only gathered periodically for individuals or products to be harvested are also farmed, but in a less intensive manner (see: **Free-range animals**). A term like 'ranching' would be more appropriate for this activity. **Zoo animals**, being undomesticated, are not regarded as being farmed.

P.246

People breeding animals for sale as actual or potential breeding stock would generally describe themselves as breeders rather than farmers.

Many attempts have been made to add to the number of species that are farmed. **Wild animals** can be farmed, and this process involves the confinement of animals that have not been selected for their tolerance of husbandry. This kind of farming can pose serious welfare issues, but the high value of many of the products (such as bear bile, musk and gourmet meats) provides a strong financial inducement.

Small animals such as **rabbits** and **guinea pigs** have been popular with rural development specialists seeking to establish new income-generating activities for rural people in the developing world. In the developed world, **game animal** farming (mainly of red **deer** and fallow deer) is a well-established alternative farm enterprise. Farming of fish and shellfish (molluscs and crustaceans) is locally very important. The longest-established aquaculture systems are probably those of China, where ponds are stocked with complementary species of carp, and the system is integrated with the farming of crops, **pigs** and ducks. More than 220 aquatic species are now farmed and, in 1997, 29 million t of fish supplies came from this source, while the catch of wild fish was 95 million t (Naylor *et al.*, 2000).

The use of farm animals has changed radically over the last 200 years as industrial societies have developed. In the developed world today, farm animals are primarily producers of commodities (meat, milk, eggs and, to a much lesser extent, wool). As such, emphasis is on the production of young animals for **slaughter** or for an unnaturally brief life as an egg or milk producer. Previously, the main value of livestock was in the form of the adult animal, yielding products and services such as milk, eggs, wool, manure and labour during as long a life as possible. Also, herds and flocks were smaller, there were more intense and individual relationships between the animals and their carers, and farm animals in general were much more integrated into human society.

These changes are particularly clear in the case of chickens. Before the industrialization of farming, these were essentially farmyard scavengers, though certain aspects of their biology have proved fundamental to the development of modern poultry industries (Hall, 2004). In a sense, they have undergone a second, technology-led, form of domestication. They are, at least physically, very adaptable to novel feeding and housing conditions and incubation can be mechanized, while their reproductive attributes suit them for intense selective breeding. They have high fecundity, a short generation interval, eggs that remain fertile in storage and sex-linked plumage characteristics, all of which promote rapid response to selection. Sexual maturation and egg laying respond to artificial light, so the seasonality of egg production can be abolished.

On a global scale, farm animal production is changing in complex ways (Owen *et al.*, 2004). In the developed world, production is growing only slowly, and many markets are becoming much more concerned with issues of product quality, especially in relation to animal welfare and food safety. In the developing world, as incomes rise demand is increasing. It is predicted that in 2020 China will consume one-third and India one-fifth of global milk production. Thus we can expect to see a great intensification of animal production in the developing world. At the same time, the problem of rural poverty in the developing world demands solutions. Farm animals would be expected to play a big part here, but local production can easily be threatened by the cheap imports made possible by a globalized market system. Certainly, farm animals are vital for draught power in the developing world, and they have much to contribute to rural development, provided the benefits reach the poor. World changes in livestock numbers are illustrated in Table F.1.

Assuring consistency between censuses is never easy, but some comparisons can be made (Hall, 2004). The most dramatic changes have been in the avian species. Increases in goats have mainly been seen in China and India and, as global trade in goats is small, the increases have been in production for local consumption. Pig numbers have increased, while international trade has increased at a greater rate. The rise in cattle numbers reflects increasing demand for milk, at least in the developing world, while in developed countries the increase in milk supplies has come from increased yields. Sheep generally use land that could support crops, and their decline presumably reflects competition for this resource, though patterns of change differ greatly between countries. Horse numbers have increased in richer countries while declining in the less wealthy. Some developing-world countries are particularly dependent economically on livestock exports, and these might be especially vulnerable to globalization (see Table F.2).

Some wealthy countries are big exporters of live animals, such as France (US\$1.6 × 10⁹ in 1999) and Canada (US\$1.0 × 10⁹) (CAB International, 2002). All these patterns of trade can change rapidly in response to exchange rate fluctuations, disease outbreaks and market developments generally.

Livestock systems are often closely integrated with the rest of agriculture. Before artificial fertilizers became widely used, manuring by livestock was vital for adequate crop yields, and crops and animals were farmed in rotation systems of various degrees of sophistication. In much of the world this no longer

P.247

applies, and now crop and animal systems are physically separated, though animal industries are often

vertically integrated so production of feedstuffs is contractually linked with production of animals for slaughter. However, crop husbandry leads to large quantities of crop residues (world annual crop production has been estimated at about 2750×10^6 t, and crop residues 3750×10^6 t; Smil, 1999), much of it ideal for feeding to ruminant livestock. Technical innovations to ensure this material is fully exploited are highly desirable.

Table F.1. World livestock populations, 1992-2001 ($\times 10^6$) (from CAB International, 2002).

Species	Population (1992)	Population (2001)	Percentage change
Donkey	43.7	42.0	-3.89
Water buffalo	153.1	167.6	+9.50
Cattle	1,302.8	1,360.1	-4.41
Goat	597.6	693.5	+16.00
Horse	60.3	58.3	-3.40
Pig	869.6	927.7	+6.68
Sheep	1,161.3	1,059.1	-9.80
Camel	18.2	19.1	+5.17
Other camelids	5.41	6.20	+14.50
Mule	15.1	13.5	-10.40
Rabbit	519.7	481.6	-7.33
Rodents	22.9	14.9	-34.90
Chicken	11,500.0	14,700.0	+27.30

Duck	652.1	915.4	+40.40
Turkey	223.4	241.4	+8.04
Geese	163.5	240.6	+47.20
Beehives	57.9	58.9	+1.68

Table F.2. Countries with the highest dependence on live animal exports, based on FAO data from 1999 (from CAB International, 2002).

Country	Total merchandise exports (US\$ × 10 ⁶)	Live animal exports (US\$ × 10 ⁶)	Live animal exports/total merchandise exports (%)
Somalia	150	62	41
Chad	211	33	16
Sudan	596	87	15
Mali	665	95	14
Niger	276	29	11
Burkina Faso	255	20	8
Mauritania	448	33	7
Namibia	1246	83	7

Farming of animals in high density always poses environmental challenges, whether it be the engendering of new diseases, the accumulation of veterinary drug residues in people or the environment, the disposal of large quantities of dung and other wastes or the destruction of natural habitats to provide land for

production of animal feeds. But this is not new. In many smallholder systems, livestock are so intimately associated with human habitation that diseases arising in one species can easily pass to another; this is the source of novel influenza viruses.

Generally, livestock production is the responsibility of ministries of agriculture, with environment and public health being overseen by other ministries, while non-governmental organizations may be the principal ambassadors for animal welfare (Wickens, 2001) and for the conservation of farm animal genetic resources (Hall, 2004). Whether this system of governance, which is often adversarial, is in the best interests of society as a whole is debatable. Similarly, agriculture is not usually held accountable for the environmental damage it does, nor is it often recompensed for the environmental protection and **conservation** it frequently provides. In the developed world these issues are beginning to be addressed.

Recent rates of subsidy for agricultural activities (US\$82,500/km²/year in the European Union (EU); James *et al.*, 1999) are unlikely to remain so high for much longer (in the USA the corresponding figure is US\$16,100). Also, with recent developments in the EU agricultural regime, the relevance and emphasis of extensively husbanded livestock is being shifted towards maintenance of landscapes, and this will lead to extensification. However, the bulk of livestock production will come from intensive farming, though niche markets for more traditional products will develop further.

The diversity of livestock **breeds** provides the genetic resources necessary for sustainable development of livestock husbandry, and it is very important that this biodiversity, which is recognized by the 1993 Convention on Biological Diversity, should be conserved and characterized.

Intensive livestock production is often, perhaps almost always, inimical to animal welfare as it is conceived today, especially when this is assessed in terms of the need of the animal to practise normal behaviours that are important to it. While good welfare can add to the value of animal products in some markets, for the vast majority of consumers and opinion leaders the welfare of farm animals is of secondary importance to economic considerations. Meat quality, for example, can be demonstrably better in animals kept and transported in good conditions, but the growing importance of food processing means that the economic incentive for enhanced animal welfare is diminishing.

Classical animal breeding, based on performance recording and **selection** (e.g. Simm, 1998; Hall, 2004) can be extremely rapid in achieving goals, and gene technology is opening up new possibilities (see: **Transgenics**). Societies are more willing to accept novel technologies when the result is new medical treatments or products, and are generally less so when the outcome is increased profit from greater yields of milk, meat, eggs, etc. There is much scope for bioethicists to lead debate on innovations in animal breeding (Mephram, 2005).

The farming and keeping of animals under domestication has led to a new kind of interspecies relationship, to add to the familiar catalogue of **predation**, **parasitism**, symbiosis, etc. Artificial **selection** has replaced **sexual selection** and, to a great extent, natural selection as a determinant of the **genotype** of animals. Although under domestication there have been very extensive genetic changes in the skeleton, patterns of fat and muscle deposition, organ size, reproductive characteristics and certain aspects of behaviour, some aspects of the phenotype have remained relatively unchanged. For example, some behaviours such as nest building in sows and the motivation of **mink** to swim remain prominent in farmed animals, in spite of long histories of husbandry.

The science of applied ethology (Jensen, 2002) was developed in order to understand the behaviour of farm and other captive animals. In parallel with insights from veterinary medicine it has enabled welfare to be assessed objectively and production systems improved. **Anthrozoology**, the study of human-animal interactions, is a growing area that also contributes to farm animal welfare, as well as to the understanding of the requirements of **companion animals**.

Farming of animals

Animal domestication can be viewed as a process by which captive animals adapt to humans and the environment that they provide for the animals. Since domestication implies change, it is expected that the **phenotype** (observed characteristics of the individual as they have developed under the combined influence of genes and experiences) of the domesticated animal will differ from the phenotype of its wild counterparts. Adaptation to the captive environment is achieved through genetic changes occurring over

generations, and environmental stimulation and experiences during an animal's lifetime. Thus domestication can be viewed as both an evolutionary process and a developmental phenomenon.

The environments of modern farms may differ markedly from the natural habitats of the ancestors of today's farm animals. Furthermore, today's farming systems are highly variable. The least restrictive of these is rangeland systems, in which animals are generally confined only by fences and have limited human contact, whereas the most restrictive systems house animals individually or in dense groups indoors, at times with bouts of intense human contact. Within all systems, there can be a range of conditions provided that markedly impact on the behaviour, productivity, **health** and **welfare** of the animals, ranging from the simple provision of water and food for rangeland animals to highly sophisticated environmentally controlled sheds where temperature, humidity and light may be tightly controlled, as well as food and the social environment.

The desire by consumers and governments in Western society in the post-World War II period for cheap and safe food has driven improvements in housing and production methods to increase animal productivity, improve the quality of food and lower the cost of food. However, there appears to be growing public concern about livestock production in terms of the effects on human health and safety, environmental effects, **intensification of animal production**, welfare of livestock in general and genetically modified foods and feeds for livestock. It is likely that these strong and, at times opposing, economic, health, environmental and ethical forces will continue to drive changes in livestock production. The need to produce cheap and safe animal products will remain, but a range of social issues will shape livestock production.

History of farm animal domestication

An important behavioural trait that influenced the domestication of ungulate and galliform species was their social organization: these species could live in relatively large groups without marked year-round **territoriality**. The formation of the social **hierarchy** or social organization in many of these species is considered to be an important mechanism that functions in controlling **aggression** and so allowing these animals to be kept in large groups with fewer chances of injuring one another or expending large amounts of energy competing for resources, such as mates or feed, that may be limited. This trait has been further emphasized through artificial **selection** during domestication. Other traits that have favoured domestication - and, in particular, livestock production - include: (i) promiscuous **mating behaviour**, in which males can mate with large numbers of females; (ii) early **bonding** between dam and offspring, which allows the offspring to remain in the **social group**; (iii) **precocial** young, which allows the young to join the social group early; and (iv) high **adaptability**, which allows these animals to adapt to a range of environments, and thus they do not require highly specialized requirements.

Wild **sheep** (*Ovis orientalis*) and **goats** (*Capra agagrus*) appear to have been domesticated at about the same time in the Near East - around 11,000 YBP - while remains of domesticated cattle (*Bos primigenius*) and **pigs** (*Sus scrofa*) are first seen in archaeological records around 8000-9000 YBP at various sites in Asia. **Horses** (*Equus feus*), **asses** (*Equus africanus*), **camelids** (*Camelus* spp.), **water buffalo** (*Bubalus bubalis*) and **chickens** (*Gallus gallus*) all appear to have been domesticated in different parts of Asia and North Africa about 5000-7000 YBP. In the New World, llamas and alpacas (*Lama* spp.), **guinea pigs** (*Cavia* spp.) and turkeys (*Meleagris gallopavo*) underwent a similar process at various times and locations.

Some authors have suggested that it is unlikely that Paleolithic and Neolithic people consciously domesticated animals for specific economic or practical purposes. Domestication in the early stages was therefore perhaps largely an unconscious process on the part of humans, in which tame or semi-tame wild animals were gradually brought under increasing levels of human control. Furthermore, different species may have been domesticated in different ways. For example, species that could be herded, such as the wild ancestors of domestic sheep, goats and llamas, would have been followed and hunted by these

nomadic human groups long before people began to play an active role in guiding the movements of the animals, protecting them from predators or interfering

P.249

selectively in their **reproduction**. Large and potentially dangerous animals, such as wild cattle, may have been coaxed gradually into semi-dependent relationships with humans by the provision of salt licks close to villages. Other species such as **dogs**, pigs and poultry may have been captured or collected when young and then kept primarily as **pets**.

The relationship between humans and domesticated animals is sometimes viewed as a successful '**adaptive strategy**' in an evolutionary sense, a kind of symbiosis in which both humans and the animals have benefited. The notion is often used to justify the use of domestic animals by humans, and is supported by the fact that most domestic animals are more numerous nowadays than their wild ancestors, some of which are extinct. While the argument may be most applicable for **companion animal** species (such as the dog and cat), the notion of symbiosis is less persuasive in relation to farmed food animals. Nevertheless, the relationship between humans and animals in modern agriculture has components of symbiosis in that, in return for the animal products or results that they provide for humans, the animals are maintained and cared for by humans, although the appropriate standards of welfare that should be afforded to these animals is contentious.

Domestication process

Some authors have noted that domestication is a process rather than an event, and that it is difficult to define the point at which a tame or captive wild animal can be classed as domesticated. In general, truly domestic animals exhibit some obvious genetic divergence from the ancestral 'wild type', due to the effects of artificial selection over many generations.

The main genetic changes influencing the development of the domestic **phenotype** result from artificial selection, natural selection in captivity and relaxed selection. Artificial selection has generally focused on productivity characteristics, and there are numerous examples of remarkable gains in many production traits in farm animals in recent decades. Growth rate of broiler chickens and pigs and milk yield of dairy cows have all dramatically increased over recent decades through artificial selection. Several specific behavioural characteristics have also been selected. Selection of silver foxes for nonaggressive behaviour towards man commenced in the late 1940s in Siberia. As a result of this selection, foxes can now be bred that show few defensive responses to people, presumably because they are less fearful. They consequently resemble domestic dogs in their behaviour, with the unselected control population continuing to exhibit wild-type behaviour, including strong defensive responses towards humans.

All of the selection imposed on captive populations that cannot be ascribed to artificial selection must be 'natural'. Animals selected to be parents of the next generation may not always reproduce and, if they do, they do not always provide the theoretically expected number of offspring. Reproductive failure may result from physiological or psychological **stress** caused by such factors as sensory and locomotor deprivation, social incompatibility, dietary deficiencies and **parasitism**. Thus natural selection has also operated on farm animals.

In many cases, relaxed selection can be expected to accompany the transition from the wild to **captivity**. Certain behaviours important for survival in nature (e.g. food finding and **predator avoidance**) may lose much of their **adaptive** significance in captivity. As a result, both genetic and phenotypic variability for such traits are likely to increase. In comparison with beef cows, dairy cows that typically have their calves removed at birth exhibit less intense **maternal behaviour** - less licking of newly born calves and less stationary behaviour during teat seeking by the calf are apparent in dairy cows. There are some very obvious examples in farm animals where domestication has resulted in the deterioration in some **fitness** characteristics. Artificial selection for large breast size in domestic turkeys has nearly eliminated the

ability of males to copulate naturally, and females require **artificial insemination**. Artificial selection of laying hens for non-broody behaviour has resulted in strains of chickens that normally do not incubate eggs or brood chicks.

Although there are many reported differences between wild and domestic stocks, there is little evidence that domestication has resulted in the loss of behaviours from the species repertoire or that the basic structure of the motor patterns for such behaviours has been changed. In nearly all cases, behavioural differences between wild and domestic stocks are quantitative in character and best explained by differences in response thresholds. These comparisons are difficult because of problems in both determining an appropriate wild population and interpreting differences between wild and domestic populations under one environment, in nature or in captivity. However, studies of farmed and wild Atlantic salmon (*Salmo salar*), both reared in either captive or wild environments, indicate that farmed salmon show fewer predator responses, while also showing increased growth, increased disease resistance and decreased stress responses.

The absence of certain 'key' stimuli in the physical environment of farm animals can influence adult behaviour. For example, social experience during rearing markedly affects the development of the **sexual behaviour** of boars, while heterosexual sexual experience influences the sexual behaviour of rams.

As discussed earlier, an important behavioural trait that influenced the domestication of farm animals was their social organization. The formation of social hierarchies or social organization in many of these species allows these animals to be kept in large groups with fewer chances of injuring one another or expending large amounts of energy competing for resources, such as mates or feed, that may be limited. This trait has also been further accentuated through artificial selection.

However, research on the effects of domestication using, for example, domestic **rodents** as a model, suggests that while the response thresholds for **agonistic behaviour** may be readily modified by early experience, response thresholds for defensive agonistic behaviour have been increased during domestication. It was a common belief for many years that the aggressive behaviour of the Norway rat (*Rattus norvegicus*) had been so reduced by domestication that what fighting behaviour remained was relatively immature and seldom resulted in physical harm to opponents. However, under certain rearing and stimulus conditions, the attack and other offensive aggressive behaviours of domestic Norway rats can be just as intense as those of their wild counterparts. It is the defensive behaviours of Norway rats that have become attenuated by the

P.250

domestication process, perhaps as a correlated effect of selection for ease of handling.

Unless wild animals have been habituated to the presence of humans, they tend to avoid close contact with humans. In captivity, the capacity to adapt to the presence of people and frequent handling is an important fitness-determining factor.

The two types of learning, conditioned **aversion** responses and **habituation** to humans, occurring both early and subsequently in life, are probably the most influential factors affecting the behavioural responses of farm animals to humans. Through **conditioning**, the **fear** responses of farm animals to humans are regulated by the nature of the experiences occurring around the time of interactions with humans. Thus farm animals in situations in which they frequently interact with humans may, through conditioning, associate humans with rewarding and punishing events that occur at the time of these interactions, and thus conditioned fear responses to humans may develop. Reduced fear of humans may also be achieved by positive associative conditioning, in which the animal's fear of humans is reduced by the latter's role as a secondary reinforcer. As providers of such necessities as food, water, shelter and grooming, humans become secondarily associated with such positive stimuli and the threshold for avoidance behaviours is raised. Over time, young domesticated animals that may have had limited experience with humans may habituate to the presence of humans and thus may perceive humans as part

of the environment without any particular significance. Habituation will occur over time as the animal's fear of humans is gradually reduced by repeated exposure to humans in a neutral context; that is, the human's presence has neither rewarding nor punishing elements. Even wild strains of rats and deer that are highly fearful of humans will habituate to humans over time.

The presence or absence of certain stimuli, intraspecific aggressiveness and interactions with humans can have profound effects on the development of specific traits in farm animals. It appears that these factors, together with genetic changes accompanying domestication, can also contribute to more general traits in farm animals. For example, it has been argued by some that the single most important effect of domestication on behaviour is reduced responsiveness (i.e. sensitivity) to environmental change. This characteristic is observed in most populations of farm animals and encompasses a wide variety of behavioural traits such as the response to novel stimuli, intraspecific interactions and response to the presence of humans. Reduced responsiveness to environmental change can be seen as an adaptation to living in a biologically 'safe' environment in which there are limited opportunities for perceptual and locomotor stimulation, frequent invasions of personal space, with little opportunity to escape from dominant conspecifics, and frequent association with humans, who are prone to cull individuals that are difficult to inspect and handle.

Failure to adapt

The process of farm animal domestication implies a transition from nature to captivity. However, 'nature' and 'captivity' are only extremes on a continuum. Free-living wild populations are found in environments ranging from wilderness areas to semi-wild preserves where animals are protected or managed and supported to some degree. Captive populations are found in environments ranging from small laboratory cages to complex zoo enclosures to large breeding parks or corrals.

Farm animals are sometimes provided with an environment that is physically similar to the habitat of their wild ancestors. Behavioural and physiological adaptations to such an environment will be readily achieved. Very often, however, the captive environment does not match the ancestral environment and **adaptability** is challenged. Welfare problems and indeed productivity problems may arise, although behavioural and physiological responses are earlier and more sensitive indicators of adaptation to the environment than productivity.

Impact of domestication

Several authors have emphasized that domestic animals are not inferior or degenerate animals in comparison with wild animals - they are simply adapted to a different environment than that of their wild counterparts. Behaviours that may be considered to have been lost through domestication are usually expressed when the right key stimuli or experiences are provided. In most cases, behavioural differences between wild and domestic stocks are quantitative in character and best explained by response thresholds. Once a species has become adapted to its captive environment, reproductive and growth rates are typically enhanced through improved nutrition, health and climate, reduced energy expenditure and, in some cases, reduced stress in captivity.

Farrowing crate

For hundreds of years, farrowing accommodation for domestic sows remained much the same: a bedded indoor or outdoor pen. However, with the intensification of animal production in the 1940s, the concept of the farrowing crate was developed, its aim being to reduce the amount of space within which the sow and her litter could be kept, while reducing piglet deaths from overlying (crushing), a major source of pre-weaning mortality. In the 1940s and 1950s the sow occupied the crate for a few days before and after **parturition**. By the 1960s crates had increased in popularity, and were used to house the sow and litter for the entire lactation. Initially, farrowing crates were constructed of wood, which wore badly and was difficult to clean. Subsequently a variety of materials was tried, including bricks and concrete, before the advent of the metal crate.

Currently, a typical farrowing crate is a rectangular metal structure, a little larger than an 'average' sow's body size. Thus, the crate may be too short or small for large, old sows (which continue to grow during their reproductive life), while too roomy for gilts and smaller sows, which may be able to turn around inside. Each crate is situated within a pen, and farrowing rooms will commonly contain multiple pens.

Piglets can

P.251

move freely through both the sow's crate area and the remainder of the pen (which will sometimes contain a heated and/or bedded 'creep' area), while the sow is fixed in one place. The pen floor may be slatted or perforated, partly slatted or solid, and will sometimes contain bedding such as straw. A feed trough and usually a separate drinker will be incorporated for the sow. Sows are generally moved to the crate from gestation accommodation a few days before they are due to farrow, and remain there until the piglets are weaned, often at about 3-4 weeks of age, although crates may be used for a shorter period (e.g. until only a few days after parturition). Piglets are most vulnerable to overlying and other causes of death during their first 2-3 days of life.

There are many variants on this 'typical' crate design: its sides may be straight, sloped or skirted, its top may be flat or peaked and its bottom bars may be straight or 'fingered'. Hydraulics (which allow the crate sides to move outwards as the sow lies down, providing more space) and floating bars may be included, as well as additions such as the 'blowaway', which emits a puff of air over the piglets as the sow lies down, in theory to encourage them to move out of the danger area beneath their mother's body. In practice, few of these design variants are based on research, but have arisen due to manufacturers' and farmers' guesswork or hunches.

The farrowing crate is undoubtedly a helpful management tool, especially in larger pig units. It confines the sow in one place, allowing piglets to be easily handled without risk of worker injury by a protective sow. In low-labour systems, crates are often combined with slatted floors and no bedding, reducing the need for cleaning.

Crates do appear to have some beneficial effects on piglet mortality. In the UK, pre-weaning mortality levels averaged 25% in 1966, but had dropped to around 10-15% by the mid-1990s, largely due to the widespread use of farrowing crates, although a corresponding decrease in weaning age over this time

period must also be taken into account. However, movement restriction and lack of exercise may impede the progress of parturition, leading to increased numbers of stillbirths. It has also been suggested that crate use changes the nature of piglet crushing, with fewer piglets becoming trapped under their mother's rear end but more beneath her chest.

The effects of farrowing crates on sows' behaviour and welfare are less positive. Crate use violates at least one of the five freedoms, the freedom to express normal behaviour, for although the occupant can stand up, lie down and roll over, it provides insufficient space to allow turning around, a behaviour commonly exhibited by unrestrained sows around the time of birth. Two more of the 'freedoms' (freedom from discomfort and freedom from fear and distress) are also threatened, as detailed below. An early version of the five freedoms, recommended in 1965 in the **Brambell Report**, stated that 'an animal should at least have sufficient freedom of movement to be able without difficulty to turn around, groom itself, get up, lie down and stretch its limbs'. Standing up and lying down are often more difficult in farrowing crates: the lack of space means that sows are unable to perform normal sequences of these posture changes, and may result in an abrupt final drop of the sow's hindquarters during lying down - which can endanger piglets - rather than a gentle and controlled lowering. The lack of space (and usually absence of substrate) prevents the sow from performing normal prefarrowing nesting behaviour (**see also: Sow behaviour**), which may lead to distress. Sows' responses to confinement in the farrowing crate may depend on their gestation environment: several authors have reported that freedom during gestation is likely to lead to increased agitation upon being placed in a farrowing crate.

Several alternatives to the farrowing crate exist, the simplest being the indoor bedded pen, which may incorporate rails or other piglet protective devices. Such pens can be very successful, particularly if they are sufficiently large, well designed and attended by skilful caretakers, but at least in the UK their use tends to be confined to smaller, less intensive units. Outdoor pig production thrives in many countries, and farmers achieve acceptable levels of pre-weaning mortality by accommodating farrowing and lactating sows in bedded arcs or huts. Variants on the conventional farrowing crate, such as the ellipsoid crate, Freedom crate and Ottawa crate, have been designed, with the aim of protecting piglets but allowing sows more freedom of movement. These designs have seen limited success, probably because of the extra space and labour required. Similarly, a voluntary crate, which the sow leaves for food and exercise, has so far gained little popularity.

Fear

Fear is an emotional reaction, induced by the perception of stimuli associated with danger, which leads to protective defensive reactions. Fear-inducing stimuli may include novelty, threats to which animals have been exposed over evolutionary time, intense stimuli, social signals and stimuli that have acquired fear-inducing characteristics through learning (Gray, 1987). Because fear is an emotion, it can be viewed as an adaptive system of coordinated changes in behaviour, physiology and cognition. In defining and measuring fear, it is important to take into account the types of stimuli to which an animal is reacting, the quality of an animal's earlier experiences with these stimuli, the type of behavioural and physiological responses the animal shows and the consequences of these reactions at both the proximate and ultimate levels. In **applied ethology**, emphasis has often been put on fearfulness, a **personality** trait reflecting the general

tendency to show fear responses to different threats (**see also: Temperament**). However, different fear responses may not be correlated and the reaction shown by the animal may depend on specific characteristics of the eliciting stimulus.

Several cognitive processes are central to the concept of fear. Perception of threatening stimuli leads to a focusing of **attention**, **arousal** and comparison of the stimuli with memories of earlier experiences, followed by decision making and the coordination of behavioural responses. Fear is expressed behaviourally as suppression of other behavioural systems and attempts to avoid, terminate or escape exposure to threatening stimuli. In some cases, fear may also be expressed as immobility or defensive attack, the specific response depending on situational variables and species as well as on the animal's predisposition to a reactive or proactive **coping** style.

P.252

Immobility may be observed either when an animal has the possibility of hiding from, and thus escaping detection by, a predator or when it is held by a predator and has no possibility of escaping. Defensive attack may be shown by some species in the close proximity of a predator or **conspecific** when the chances of escaping are low (**see also: Aggression**).

Fear is also associated with a range of physiological and endocrine responses characteristic of activation of the sympathetic-adrenal-medullary and **hypothalamic-pituitary-adrenocortical (HPA)** axes. These include both neuroendocrine (adrenaline, noradrenaline, corticotropin-releasing factor, adrenocorticotrophic hormone (**ACTH**), **glucocorticoids**, beta-endorphin) and physiological (**blood pressure**, changes in **heart rate** and heart rate variability, stress-induced hyperthermia) changes generally associated with **stress**.

The central nucleus of the amygdala is among the most important centres of the **brain** mediating fear responses. It has connections to many other areas of the brain, including the **hypothalamus**, dorsal motor nucleus of the vagus, parabrachial nucleus, *locus coeruleus* and paraventricular nucleus. Neural systems implicated in fear include noradrenergic, dopaminergic, serotonergic and GABAergic systems. Pharmacological treatments aimed at alleviating fear typically target GABAergic systems using **benzodiazepines** such as diazepam and chlordiazepoxide, or the serotonergic system using drugs such as buspirone.

The diversity of empirical correlates of fear, as outlined above, underpins the fact that fear may be ascribed to animals on the basis of well-defined behavioural and physiological criteria without implying that the animal must be undergoing the same kinds of conscious experiences that a person might have. However, although the animal's subjective experience is by definition inaccessible to an outside observer, it is normally assumed that fear is experienced as uncomfortable and therefore detrimental to welfare. Under conditions to which an animal is well adapted, fear responses protect the individual from exposure to damaging stimuli. On the other hand fear is typically associated with the activation of systems mediating physiological stress, and prolonged exposure to fear-eliciting stimuli may therefore function as a chronic stressor.

Fear versus anxiety

It is useful to distinguish between fear and **anxiety**. Whereas the former is a response to stimuli associated with real and immediate danger, the latter is a response to stimuli associated with potential or more ambiguous danger. Although it may not always be easy to stringently separate the two, empirical justification for the distinction between fear and anxiety can be found in the work of Blanchard *et al.* (1990), who studied rats living in visible burrow systems. Rats exposed to the actual presence of a predator - and thus a real danger - initially flee and become inactive. In the absence of an escape route, rats may freeze or exhibit defensive threat or attack, the latter behaviour becoming more predominant with the increasing proximity of the predator. This type of behaviour, given the context, may be

considered as indicating a state of fear, which functions to ensure survival in the face of immediate threat.

On the other hand, rats exposed to an area in which they have previously encountered a predator - a situation clearly indicative of potential danger - engage in cautious approach and investigative risk assessment behaviour. The perception of mild threat thus causes a general increase in anxiety that helps to locate the source and type of danger and to plan possible ways of dealing with it (Marks and Nesse, 1994). In addition to justifying the conceptual distinction between fear and anxiety, the above example partly illustrates that fitness may suffer if fear and anxiety reactions are deficient, excessive or inappropriate in form (Marks and Nesse, 1994).

Fearfulness

Fearfulness is a component of personality and can be defined as the propensity to perceive and react in a similar way to a variety of threatening or potentially threatening stimuli (Boissy, 1995). Measurement of fearfulness presupposes that the measured variables provide information about stable characteristics of an individual that can be generalized to other times and other similar situations. This is different from measures of fear that may sometimes be very specific to a given situation and may not show stability over time, but change according to situation-specific variables. As an example, avoidance of a novel and conspicuous object will lead to a reduction in fear over time, but the animal's general fearfulness will remain stable and influence behaviour in the same way the next time it is exposed to a similar situation.

Fearfulness is influenced by both genetic and environmental factors. The effect of genetics is documented by a large number of **selection** experiments. Fearfulness is also one of the characteristics that have been altered through **domestication** and selection for production characteristics, as illustrated by the fact that thresholds for the elicitation of different fear responses are normally found to be lower in ancestral animal breeds than in modern production breeds. On the other hand, a basal level of fearfulness has been maintained in all domestic populations because of the importance of this personality trait for survival. Fearfulness is also continually modulated by pre- and postnatal developmental processes, as well as by learning. Prenatal stress increases fearfulness and early postnatal stress may reduce fearfulness. These effects may be very dramatic. There are therefore two major ways in which fearfulness may be reduced in efforts to improve welfare in domestic animals, through either genetic selection or manipulation of the prenatal or postnatal environment.

Cost and benefit of fear

Under extensive production conditions, **predation** by carnivores may be considerable, and normal fear reactions may play a role in determining which individuals survive. Breeds showing more adaptive defensive reactions may be better suited than others. Even under intensive production conditions, many common stockmanship procedures, such as herding, often presuppose that animals avoid humans. A **stockperson** may sometimes treat animals that do not avoid him or her abusively, thus reinforcing learned avoidance reactions. On the other hand, research within applied animal behaviour has focused largely on the negative implications of intense and chronic states of fear and anxiety in farm animals. Because farm animals are widely protected from predation, fear and anxiety elicited by contact with humans and other environmental stimuli are generally considered unnecessary and maladaptive, reducing production and welfare under normal

P.253

production conditions. Hypotheses predicting fitness-reducing effects of fear and anxiety may be formulated in terms of exaggerated and prolonged activation of stress-mediating endocrine systems, as interfering with cognitive functioning or as redirecting attention away from a task at hand towards stimuli eliciting fear or anxiety.

Measuring fear

Methods used for measuring fear and anxiety may involve the quantification of both conditioned and unconditioned behaviour. Conditioned responses involving conflict include the fear-induced inhibition of food-reinforced lever pressing, water-reinforced licking and food-reinforced key pecking. Unconditioned responses involving conflict that have been used as indicators of anxiety include behaviours in the **approach test**, **social interaction test**, **elevated plusmaze**, **light-dark test**, **open-field test** and **novel object test**, as well as a diversity of other specific tests. Aversively stimulated behaviours that have been used for studying fear include fear-potentiated startle, **vocalization** (separation distress, vocalization in response to pain, startle, attack and drug withdrawal), defensive burying, stress-induced hyperthermia and stretched approach posture, in addition to a range of other species-specific responses.

Several of the tests mentioned above are based on the observation of **conflict behaviour**. Animals have competing motivations to avoid and approach dangerous stimuli. The acquisition of information about the degree and type of danger facilitated by approach and investigation is crucial to survival because it allows the animal to show adaptive stimulus-specific responses. Animals forced into close proximity to dangerous stimuli primarily show immobility, desperate escape attempts or aggressive behaviour. Tests using forced exposure to **aversive** stimuli can be used to assess the form of fear responses, but may have limited utility in assessing the level of stimulation at which fear is elicited in different individuals. The threshold of stimulation at which fear reactions are elicited can more easily be assessed by the voluntary approach and avoidance behaviour expressed by a freely moving animal.

The observation that freely moving animals withdraw from threatening stimuli when the motivation to avoid becomes stronger than the motivation to approach is formalized by Miller's model of **approach-avoidance conflict** (reviewed by Gray, 1987). The model implies that tendencies to approach dangerous or potentially dangerous stimuli will be inhibited by fear or anxiety at a distance from stimuli at which the motivation to avoid becomes stronger than the motivation to approach. The strength of both approach and avoidance increases with increasing proximity to the object, but the strength of avoidance increases more rapidly than the strength of approach. Miller's model thus provides a framework within which to evaluate the relative levels of stimulation at which fear and anxiety responses are elicited based on the approach and avoidance behaviour of freely moving animals responding to dangerous or potentially dangerous stimuli.

Validity

Many of the tests commonly used to quantify fear responses are subject to very little validation prior to their use (**see also: Validity**). This is regrettable in that recorded measures may be very ambiguous and give little information about fear itself. In the following, fear of humans will be used as an example of how measures can be validated using several techniques. Tests of the internal validity of putative measures of fear of humans involve testing for predicted effects of a treatment thought to affect fear of humans. Aversive treatment by humans or medication with anxiogenic drugs prior to testing would be predicted to increase avoidance of humans in freely moving animals, as well as increasing the severity of physiological stress responses shown during forced exposure. Pleasant treatment by humans or medication with anxiolytics, on the other hand, would be predicted to reduce avoidance in freely moving animals, and reduce physiological indicators of stress during forced exposure. Confirmation of these effects on the response variable would entail a partial internal validation of the methods used for measuring fear. If measures are not affected by the treatment in the predicted direction, either the sensitivity or the internal validity of the putative measures of fear may be considered to be low. To test for external validity, recorded measures of fear of humans may be used to predict zootechnical performance (e.g. milk production, egg production, growth, immune function, maternal ability) or other aspects of animal behaviour that are thought to be affected by variability in fear.

If the effects of several different treatments are tested, preferably in different studies, the results can be used to evaluate the specificity (convergent and discriminant validity) of putative measures of fear of humans. Testing for convergent validity entails testing the hypothesis that alternative measures of fear are empirically related. This may involve testing for predicted correlations between alternative measures of fear. It could also involve testing the hypothesis that several different aversive treatments by humans increase fear, whereas several rewarding treatments by humans reduce fear. To evaluate discriminant validity, it would be relevant to test the prediction that measures thought to reflect different behavioural systems - such as fear of humans and aggressiveness towards conspecifics - are not correlated. This would establish that conceptually unrelated constructs are also empirically unrelated. These methods for validating indicators of fear should be used more frequently in future studies.

Challenges for future research

The state of knowledge regarding fear in farm animals has a number of weaknesses that could be ameliorated through future studies. First, there is a general lack of validation of tests used to measure fear. As part of future research, tests could be properly validated following the guidelines suggested above. There are also a limited number of studies testing for predicted associations between existing variation in fear and anxiety and production of fitness-related behavioural parameters in a number of species. Existing studies have primarily been descriptive, and have focused on documenting associations between the way in which animals are handled and their growth and reproduction. Documented associations between handling and productivity may therefore be an effect of handling on stress itself and need not be mediated by fear.

There has been a primary focus on the personality trait of fearfulness as a general response pattern, and its relevance for predicting general response thresholds and adaptability in

P.254

relation to a range of challenges. Furthermore, responses to fear- and anxiety-eliciting stimuli are rarely considered as representing distinct states and are rarely studied as adaptive mechanisms. In order to study fear responses as adaptive mechanisms it is necessary both to distinguish between fear and anxiety and to focus on differences between fear-eliciting stimuli and corresponding behavioural responses that confer an adaptive advantage.

Fear-welfare relationship

Short-lasting and adaptive fear responses are likely to safeguard an individual's welfare by leading to responses that protect it from physical damage. Chronic and exaggerated fear responses to stimuli that an animal cannot avoid, on the other hand, are likely to be associated with reduced welfare. This can be illustrated for **chickens** living in loose-housed production systems. Moderate and adaptive fear response lead to moderate avoidance of a stockperson and keep birds from being trampled under the feet of the stockperson. On the other hand, hysterical responses where birds flee and pile up at one end of the house may cause significant damage by scratching, and mortality by crushing and suffocation.

Feather

Feathers are specialized, avian, epidermal structures of which the two main types are the externally visible contour feathers and the insulating down feathers. The vane of contour feathers consists of numerous barbs, branching from the main shaft at 45°, connected to larger numbers of barbules that possess microscopic hooks that allow the barbules to adhere closely to one another. Down feathers appear fluffy because they lack these hooks and hence do not form a closed vane. The embedded feather quill occupies the follicle, to which are attached feather muscles, capable of elevating or lowering the feather. The walls of the follicle, the dermal papilla that extends into the end of the quill and the feather muscle are all well supplied with general somatic afferent nerve fibres and nociceptors.

There is behavioural and electrophysiological evidence that feather removal by pulling is painful in the domestic **chicken**. Initial feather removal results in escape behaviour and subsequent feather removal results in a passive, crouching immobility behaviour typical of chickens' response to **pain**.

Electroencephalogram recordings indicate a progressive increase in the high-amplitude, low-frequency activity following successive feather removals. This type of activity is similar to that seen in other species at times of **stress**. Chickens also show temporarily increased **blood pressure** following feather removal.

The plumage of the domestic chicken is important for insulation and prevention of **injury**, in addition to the limited flight of which it is capable. The lipids secreted by the uropygial or preen gland serve to reduce feather wear and waterproof the feathers. The secretions of the gland are spread over the plumage as part of **preening**, which tends to have a **diurnal rhythm** with peaks in mid-morning and afternoon. Both preening and **dust bathing** serve to maintain plumage quality. There is some evidence that the function of dust bathing is to remove stale lipids from feathers, increasing the 'fluffiness' of down feathers and improving their insulating properties. The feed consumption of layer hens increases as more feathers are lost, since more body heat is lost. This is of economic concern to farmers, who want to maximize the conversion of feed into eggs.

Feather loss or damage can be caused by abrasion, more common in caged hen systems than in other forms of housing. It is more frequently caused by **feather pecking** in all systems, in which one chicken pulls the feathers or pecks at the plumage of another bird. A validated and extensively used method of plumage scoring in laying hens is described by Tauson *et al.* (1984), in which the body is divided into five individually scored parts. A total score of 20 represents an undamaged plumage, whereas the lowest possible score of 5 indicates a heavily damaged plumage with no or very small areas of the body covered in feathers. The level of severe feather pecking present is known to adversely affect the plumage score, but other factors such as cage design can also have a marked effect. In most laying hen flocks, bird plumage score decreases throughout the period of lay.

Feather pecking is a widespread problem in laying hens and can also occur in caged laying hens and other poultry species. It is a **welfare** problem because of the pain associated with feather removal, the possible relationship with cannibalism and the widespread use of **beak trimming** as prophylaxis against the behaviour. It is thought that this **abnormal** behaviour is related to management conditions on farms.

Various risk factors have been identified, including large flock size, high stocking density, pelleted food rather than mash, nutritional deficiencies, poor litter quality, little access to perches during rearing, and high-intensity lighting. It is possible that by exposing skin, feather damage and loss may lead to cannibalism, when a bird will peck at the flesh of another, causing injury and sometimes death. However, the relationship between feather pecking and cannibalism is not yet clear.

It is thought that feather-eating behaviour in laying hens is a relatively common occurrence. This is a form of **pica** and can lead to crop impaction; it has been observed in hens suddenly placed in unfamiliar flocks. High levels of feather eating in reared pullets can be associated with outbreaks of feather pecking and cannibalism. However, it remains unknown whether feather eating promotes feather pecking, or vice versa.

Feather-plucking or -chewing psittacine birds, such as the grey parrot (*Psittacus erithacus*), are commonly presented in veterinary practice. This should be differentiated from feather pecking in poultry, in that the psittacine is removing its own feathers rather than those of other birds. However, this may simply reflect the fact that psittacines are more frequently individually housed than group-housed. Feather plucking syndrome can have a variety of medical and psychological

P.255

causes, which in themselves may represent a welfare problem. Wild psittacines generally live and forage in flocks. Hand rearing of young birds in isolation can result in anxiety and poor acquisition of the learned components of preening, which may lead to feather plucking. Other psychological causes, such as **boredom**, anxiety and phobias, may result from the conditions in which the bird is kept.

Some consider feather plucking to be similar to self-injurious behaviour in monkeys, in which rearing and **weaning** in isolation results in a large proportion of primates developing locomotor **stereotypies**. In these circumstances, retraining the bird or environmental **enrichment** may resolve the symptoms.

Environmental enrichments that increase foraging opportunities for parrots have been shown to increase plumage scores, in a similar way to chickens. Feather plucking may be seen following the practice of wing clipping, which prevents the bird from flying. Concern has been expressed by some avian veterinarians that the practice of clipping one wing can result in the bird injuring itself while attempting to fly. Other methods of control, involving training the bird, have been advocated.

Feather pecking (feather plucking)

Feather pecking is an abnormal behaviour found mainly in barren, frustrating and stressful intensive production environments in which the performance of a number of normal behaviour patterns is not possible. It is defined as the pecking at and removal of feathers of one bird by another, although in singly kept animals, such as parrots, self-plucking may occur. It can be further subdivided into gentle feather pecking, where the feathers are gently pecked at and nibbled but not removed, and severe feather pecking, where the feathers are vigorously pecked at and removed. It is severe feather pecking that is a **welfare** concern, as removal of feathers can cause bleeding and stimulate **cannibalism**.

There is growing evidence that feather pecking in domestic poultry (especially severe feather pecking) is related to the **motivation** for **foraging behaviour** and gut function. For example, birds kept on a substrate at which they can direct foraging behaviour feather peck less than birds kept on wire floors. High-fibre diets also result in lower feather pecking levels compared with low-fibre diets. **Chicken** feathers are considered non-nutritive, but are often consumed by the feather pecker after removal. Feather consumption has been shown to affect digestion in a manner similar to insoluble fibres, which are generally at quite low levels in a standard chicken feed. An analysis of the fixed action patterns involved in feather pecking, foraging and a number of other types of pecks found that the movement patterns involved in feather pecking were similar to those in foraging for all measures, also indicating similar underlying motivations behind those pecks. Thus, feather pecking may be a way for birds to satisfy foraging motivation and increase insoluble fibre in the diet, thus improving gut function.

However, there are many other factors that affect feather pecking. For example, birds provided with opportunities for **dust bathing** or other types of environmental enrichment also show decreased levels of feather pecking. Chickens genetically selected for high levels of feather pecking were found to have lower **serotonin** levels than those selected for low feather-pecking rates. Low levels of serotonin have been implicated in other behavioural disorders, such as depression and **compulsive disorder**. Thus, high levels of feather pecking may be indicative of a mental abnormality in birds, and this is the primary hypothesis relating to its expression in captive **pet** birds, such as parrots. Early experience also affects feather pecking. Chicks reared with a hen (a practice never seen on commercial farms) displayed less feather pecking later in life than chicks reared by a standard method. Feather pecking can be considered a stereotypic behaviour, and thus it is possible that some birds continue to feather peck even if they have been moved to enriched conditions due to perseverance of the behaviour, adding to the difficulty of solving the problem of feather pecking.

Feather pecking is a welfare concern because the removal of feathers has been found to be painful, and blood from feather removal may stimulate cannibalism. However, current methods in attempting to control feather pecking on the farm also have welfare concerns and thus are not acceptable as long-term solutions. Currently, feather pecking is largely controlled by **beak trimming** the birds and/or putting them in battery cages; in the case of parrots, a collar may be used to restrict the head movement necessary for plucking. Beak trimming, the removal of the last third of the beak, does not stop feather pecking but makes feather removal more difficult, decreasing the related cannibalism. Beak trimming has been associated with acute and chronic pain and, as the beak continues to grow, trimming may have to be performed a few times throughout the life of the bird. Battery cages or small wire cages limit contact and

even movement, which decreases the amount of feather pecking possible, but these will be banned in a number of countries, including those within the European Union, in 2012.

Feedback - positive and negative

Feedback systems are regulatory circuits that help to maintain some controlled parameters around an optimal value. This control is operated through a **signal** (a feedback loop) that is referred back to the system when some parameters change. A simple example of a feedback system at the behavioural level is the maintenance of optimal body temperature in reptiles. Reptiles are ectothermic animals that expose their bodies to sunlight to warm up. Body temperature needs to be maintained within a narrow range in order to assure the proper functioning of the organism. Therefore, a feedback system operates so that a reptile exposes its body to direct sunlight when body temperature is too low or, conversely, it moves to the shade to cool its body temperature down.

Feedback systems are observed at every biological level, from genes and cells to organisms and ecosystems. Two types of feedback may be distinguished: (i) positive feedback, where the signal tends to accelerate or increase the occurrence of a particular process; and (ii) negative feedback, where the signal operates by reducing or slowing down a process. Some degree of oscillation is a recurrent characteristic of feedback systems, resulting from either the imperfectly tuned inputs of positive and negative feedback or the fact that conditions change too rapidly or too often for the system to remain stable through feedback.

(BM)

Feeding

Feeding is perhaps the most basic, primitive and persistent of all behaviours, and makes a central contribution to most animal functions. It is due to the consequences of the action of feeding that the

animal is able to survive, grow and eventually reproduce. Like most behaviours, it allows animals to achieve their ultimate goal, that of maximization of **adaptive** fitness. While the contribution of feeding behaviour to **fitness** is accepted unquestionably for wild and unselected, extensively kept animal populations, its function and purpose for most domestic animals has been the subject of debate. This is because uninhibited feeding behaviour may lead to 'unfit' adults that are unable to reproduce. The greatly reduced reproductive ability of broiler breeders - the parents of broiler chickens - that have been fed a high-quality food *ad libitum* throughout their lives is a good case in point.

The intensive selection of domestic animals for certain traits, spectacular as its effects have been, has had only a minor effect on behaviour, including feeding behaviour, in an evolutionary context. It is artificial selection for 'unusual' traits, such as excessively high rates of milk and meat production, that has led directly to reduced fitness and not changes in feeding behaviour that have contributed to it. Nevertheless, in view of the unusual extent to which traits in domestic animals have been selected for, it is useful if the idea of fitness as a goal is broadened to account for the outcomes of feeding behaviour in such animals. It is now accepted that domestic animals have current output goals that they seek to achieve through their feeding behaviour. Such output goals include their rates of growth, milk, wool and egg production and the level of fatness. The consequences of this suggestion are, in most cases, identical to those of having fitness as a goal.

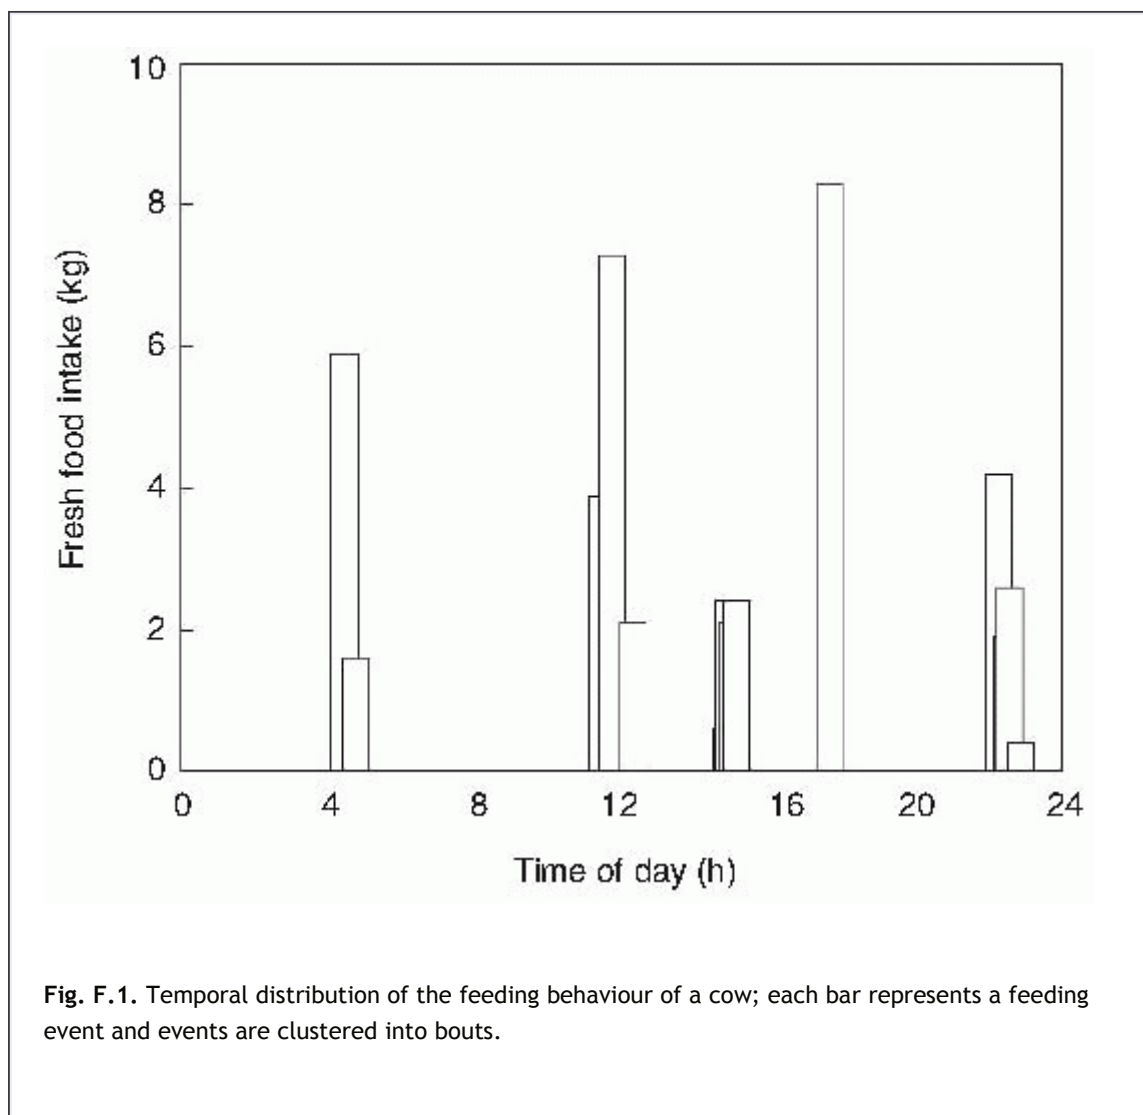

The components that constitute feeding behaviour relate to the following questions: (i) when to eat; (ii) where to eat; (iii) what to eat; and (iv) how much to eat during a particular period of time. The relevance of these questions to the feeding behaviour of the various kinds of domestic animals will depend on their system of rearing. Extreme examples are animals offered a limited amount of a particular food once daily, such as in the rearing of broiler breeders, on the one hand and ruminants in extensive grazing systems on the other; in this latter case all four questions apply. The scientific issue is how these four components contribute to the 'desire' of animals to achieve their output goals and what are the factors that modify them.

When to eat

Animals do not distribute their feeding behaviour randomly in time, but cluster it into discrete bouts. The smallest unit of feeding behaviour is an event, such as a visit to a feeding trough, during which the animal exhibits uninterrupted feeding. For foraging animals, this can consist of a number of consecutive bites or pecks taken from forage. Such feeding events are separated by time intervals of variable duration, during which feeding does not occur (see Fig. F.1 for cows). Short intervals will usually be the consequence of random events that lead to the disruption of feeding behaviour; such disruption may arise from competition or other interaction with **conspecifics**, sudden noise, etc. Feeding can also be facilitated by conspecifics, especially in young and growing animals, so that members of the group tend to feed together. Long intervals are considered to be a consequence of the

P.257

underlying physiology of the animal and its **habituation** to its environment; they are used to define a feeding bout or *meal*. A meal may be expected to start when the animal is motivated to eat - i.e. it is hungry - and to stop when the animal is satiated.

In the extreme case, the duration and size of a meal will be highly correlated with the duration of its preceding or succeeding interval: these are the widely used pre- and postprandial correlations. However, the distribution of meals is mainly dictated by a **diurnal pattern** that in turn is determined by events that are associated with the animal's management. Farm animals show increased intensity of feeding behaviour immediately after fresh food has been offered to them, around the time of **milking** and at the onset of natural or artificial lighting when the first meal of the day is eaten. Figure F.2 shows an example taken from data on pigs. The natural history of the species will dictate this pattern, as laboratory **rodents** still take their meals during darkness, and raise the possibility that feeding behaviour may have a **circadian rhythm**, i.e. it is the result of an internal clock.

While the distribution of feeding behaviour into meals seems to reflect the 'preferred' behaviour, animals are also characterized by great flexibility with regard to when to eat. For example, animals kept in hot environments modify their feeding behaviour so that most of their meals occur mainly during the cooler parts of the evening. The frequency of the meals can be affected by competition, due to the limited number of animals that can be accommodated at any one time at the feeder. Increases in animal pressure per feeder may thus increase meal frequency while decreasing meal size. In simple terms, the distribution and size of meals can be seen as the means the animals have at their disposal to achieve the goals of their feeding behaviour.

Where to eat

This option is available only to animals that are reared extensively. The question is not independent of what to eat (see below), the difference being only a matter of scale. With other things being equal, animals are expected to forage at sites that offer the highest nutrient and energy intakes per unit of effort. For example, grazing ruminants prefer tall over short swards, and swards of higher nutrient content. At the same time, animals would be expected to prefer foraging sites that minimize the risk of exposure to predators, pathogens and weather elements. The fact that both cattle and sheep avoid areas contaminated with faeces, where the concentration of pathogens is at its highest, is consistent with this view. On the other hand, site selection by sheep seems to be unaffected by exposure to cold, presumably because they have a high capacity to cope with such conditions.

In relatively unmanaged and natural environments animals are faced with the complex problem of choosing between sites that simultaneously offer benefits, such as high rate of nutrient intake, and costs, such as **exposure** to parasites. In these cases a reasonable expectation would be that site selection is the outcome of a trade-off between these benefits and costs, and that animals prefer sites that offer the

highest net benefit. This theoretical prediction has been confirmed by experiments performed on a small scale.

What to eat

This is an issue relevant only to animals that are given free and continuous access to two or more foods as a choice. The most complex choices are faced by grazing animals that are required to choose not only what plant to eat, but what specific part of it as well, e.g. stem or leaf. Less complex choices are offered to

P.258

cattle given a heterogeneous mixture of silage and concentrates, and to poultry given access to a heterogeneous mixture of cereal and a protein concentrate. In such cases the choices made by the animals are neither random nor purposeless, but appear to follow some specific rules.

Some of these rules appear to be the consequence of hard-wired behaviour and have been pre-shaped by **evolution**. Animals still exhibit innate **preferences** for sweet-tasting foods (usually sources of energy), even when these do not have an energetic value, and avoidance of bitter foods (in nature usually associated with toxins), even when the foods do not contain any toxins. Most of the rules of diet selection, however, are the consequence of learned behaviour. Such rules include the selection of diets that: (i) maximize nutrient and energy intake rate; (ii) meet the animal's requirements for energy and nutrients; (iii) minimize intake of toxins and exposure to pathogens; and (iv) reduce the likelihood of digestive disturbances. There are examples in the literature to support the evidence of behaviours consistent with these rules, provided that the animal has had the opportunity to learn about the properties of the foods offered and their consequences, and is offered choices that allow such behaviours to be exhibited. Whether these rules are followed in the long or short term will depend on the time scale of the consequences of diet selection. While meeting nutrient requirements might not matter in the short term (see below), consistent exclusion of toxins from the diet would be of significance both in the long and short terms.

In a manner similar to the choices offered during site selection, animals are frequently faced with complex food choices. These choices may include instances in which animals are given access to two or more foods as a choice, a combination of which cannot be an appropriate diet - i.e. a diet that meets all above criteria. In these cases the principles of trade-off behaviour will apply, so that the selected diet is the outcome of trading between the benefits and the costs associated with each food. These benefits and costs, however, will depend on the internal state of the animal. For example, an animal already immune to parasites may select for tall swards that are associated with the presence of faeces and hence parasites. This would be because consumption of parasites by an immune animal is associated with very small costs. Similarly, the perception of costs and benefits may be affected by the animal's motivation for food. A highly food-motivated animal would be prepared to include in its diet foods that under normal circumstances it would have either avoided or preferred to a lesser extent.

How much to eat

This is perhaps the most frequently asked question in relation to feeding behaviour, as it relates directly to the applied implications of the control of food intake and animal productivity. Given the proposition that animals will seek to achieve their current output goals through feeding behaviour, then the expectation is that they will eat as much as is necessary to achieve this and no more. When animals are given access to a balanced food, the amount of food eaten will be dictated by their output goals: fat **genotypes** will be expected to eat more than genotypes that have been selected against fatness; and animals of high-yield capacity, such as the highyielding dairy cow, will eat more than their unimproved

counterparts. This suggestion precludes the possibility that animals may be eating simply in order to derive pleasure, i.e. reinforcement from the action of feeding per se.

When an animal is given access to an unbalanced food, a reasonable expectation is that it will modify its rate of food intake in a manner that brings it closer to achieving its output goals. Therefore, when an animal is given access to a food that is low in a food resource (energy or nutrient), it would be expected to increase its food intake in such a way that the appropriate or required intake of that nutrient would be achieved. The consequence would be that animals would eat all other nutrients in excess. Pigs and chickens given access to a food low in protein have a higher food intake, and are considerably fatter, than animals on a high-protein food, presumably because they attempt to eat for protein.

It is also possible that, by attempting to eat for the first limiting food resource, the animal reaches its capacity to deal with the excess. Such capacities are defined by the animal's physiology and anatomy, and may include the capacity of the gastrointestinal tract and the maximum ability to deal with excess nutrients, such as protein, and toxins (detoxification rates). The environment also influences other capacities in which the animal is kept, such as the maximum capacity to dissipate excess energy as heat to the environment. When these capacities are met the animal will not be able to increase its food intake any further. These suggestions are well demonstrated by the changes in the intake of animals whose food intake is progressively diluted with an indigestible material (see Fig. F.3). Initially, animals increase their food intake so that their energy intake is constant. On reaching their capacity for bulk, food and energy intakes start to decline, since intake is now set to constant bulk.

The question is whether the regulation of food intake, both in terms of what and how much to eat, is achieved over the short term - on a meal basis for example - or in the longer term. When the spontaneous nature of feeding behaviour is maintained, there is very little evidence that either the amount or the composition of the food eaten is regulated in the short term in a tight manner. In farm animals there is considerable evidence for large variation in the values of the variables used to describe short-term feeding behaviour, such as number of meals and amount of food eaten per meal. Animals with similar average daily intakes can have twice the number of meals (with half the average intake per meal) compared with other animals that consume similar amounts in total. In addition, there is much evidence that changes in environmental conditions that have no effect on daily food intake can be accompanied by very large changes in short-term feeding behaviour. An example is that either an increase in the number of animals in a group with a constant number of feeders, or a decrease in the number of feeders for a given group size, almost invariably leads to considerable changes in feeding behaviour, while having little effect on daily or longer-term food intake. Short-term feeding behaviour may, therefore, be seen simply as the strategy that is used by the animals to achieve their food intake and that ensures achievement of their output goals.

Given the basic and unremitting nature of the feeding behaviour, it is hardly surprising that animals exhibit specific behavioural problems when they are deprived of its control, e.g. given restricted amounts of food. The occurrence of this is

P.259

more frequent than not, as even **pet** animals are given a defined amount of food a couple of times a day. Such behavioural problems include food-related **stereotypies**, **tail biting**, etc. and are considered to be a reflection of **redirected** (feeding) **behaviour** towards the most appropriate stimuli. In some instances feeding behaviour may be directed towards suitable foraging substitutes (such as straw bedding), but in many others the physical constraints of the environment are such that it is directed towards pens, cages or even towards conspecifics. Such behaviours are widely considered '**abnormal**' and by many as indicative of reduced animal **welfare**, and are of public concern.

Kyriazakis, I. (1997) The nutritional choices of farm animals: to eat or what to eat? In: Forbes, J.M., Lawrence, T.L.J., Rodway, R.G. and Varley, M.A. (eds) *Animal Choices*. Occasional publication of the British Society of Animal Science No. 20, Edinburgh, UK, pp. 55-65.

Feeding systems

A feeding system is a term often used in association with farming practices. In general, the feeding system describes the type of **feeding** regime adopted by the **stockperson** or owner and often encompasses the method by which the food is delivered.

Access to natural or formulated feeds varies with the feeding system adopted. For example, dairy cows may be given access to pasture alongside concentrate feeds (cereal-based feeds) during the grass-growing seasons when herbage is plentiful. When conserved forage or formulated diets are provided, they are either presented on an *ad libitum* basis or they are fed as a restricted or controlled ration. During *ad*

libitum feeding, appropriate food is freely available for self-selection by the animal throughout the day, whereas restricted feeding ensures that food provision is more controlled.

Reasons for restricted feeding vary by species. For example, the amount of concentrates fed to dairy cows may be limited due to the risk of gastrointestinal problems, and limiting the food intake of pigs can achieve a better food conversion ratio and a leaner carcass. Restriction is achieved either by reducing the amount of time the animal has to access the feed or by reducing the total amount offered at one or multiple feeding intervals. It is important to understand the feeding behaviour of the species when designing or proposing feeding systems, since this may not only affect the utility of the system, but also impact on the welfare of the animals within it. For example, if feeding is normally socially facilitated (see: **Social facilitation**) but provision is not made for such activity, intake may be suboptimal and the risk of **aggression** increased.

The method of feed delivery differs between feeding systems. The requirements of *ad libitum* systems are that all animals should have equal access to a continual supply of food and that food waste is minimized by ensuring that food stays in the feeding device or feeding area. In this type of system problems may arise due to aggression or hoarding, and thus food should be dispersed so that all individuals can gain access to the feed and no single individual or group monopolizes the food source.

Feed delivery to group-housed animals on a restricted feeding regime can be more complex, as the stockperson or owner needs to be sure that each animal is receiving no more than its allocated ration. This can be achieved by providing separate feeding stations or fitting animals with a transponder on a collar. The transponder identifies the individual when it enters the feeding area, allowing a pre-allocated amount of food to be dispensed (this may be a full daily ration or part ration depending, in part, on the natural feeding patterns of the species). The system can be programmed to dispense the food after predetermined time slots (interval schedules), which prevents animals from regularly blocking entry to the feeding system and ensures that the animal does not eat the entire ration at once. It is important to make sure that an animal cannot be displaced from the system once the food is dispensed (e.g. food is dispensed only once the animal is within a secure station and not as it enters), and that the animal can safely consume the food and leave the system (usually through a separate exit) without being injured or threatened by other members of their group.

The type of feeding system adopted is dependent upon the role or use of the animal. For example, the broiler chicken has been genetically selected for an increased rate of growth that has resulted in an increased appetite. To maintain rapid growth the birds that are destined for **slaughter** are fed an *ad libitum* ration high in protein from day one to finishing. However, breeder parents of broiler parent stock need to have their feed intake controlled, often limited to one meal per day, to prevent reduction in reproductive performance and health problems associated with rapid and excess weight gain. The consequences of this type of feeding regime for the chicken include chronic **hunger**, increased aggression between individuals and performance of **abnormal** behaviours that are indicative of poor **welfare**. This highlights the point that, in some circumstances, feeding systems can be in conflict with the natural feeding behaviour of the animals in question, since, in the case of production animals, the feeding system chosen may be

P.260

based on maximizing economic return through optimizing measures of **health** and production.

Feedlot

A feedlot is an enclosed area or building where ruminants are, generally, fattened rapidly for **slaughter**. However, animals may be put into a feedlot at other times of their life when pasture is not growing, such as during extended dry periods or when the ground is covered in snow and/or frozen. In these situations the aim of keeping animals in a feedlot is to provide them with sufficient feed to maintain, rather than increase, body weight and body condition.

The animals that enter feedlots have usually been sourced from extensive, grazing-based systems (**see: Free-range animals**) and, consequently, experience dramatic changes in their environment and management on transition to the feedlot. Additionally, animals from different properties may be mixed to comprise a pen-group, which results in disruption of social relationships (**see: Hierarchy**). Animals may have also been subjected to periods of transportation prior to feedlot entry (**see: Transport**). All of these factors contribute towards **stress** in the animals, which may reduce their immunocompetence (**see: Immune system**). This makes the animals susceptible to **disease** and it is, therefore, very important that the animals are closely monitored during the early phase of lot-feeding for signs of ill health. One major advantage of close confinement in a feedlot is that it is relatively easy for all animals to be checked for injury or signs of ill health, and this checking tends to be conducted at least daily. Thus animals can be treated promptly, reducing the duration of any **pain** and **suffering**.

The usual aim of lot-feeding animals is to improve their nutrition, which increases growth rate and the rate of fattening, and thus reduces the age at which animals can be slaughtered. The slaughter of young animals has consequences for aspects of meat quality, such as a whiter fat colour and a greater proportion of tender meat cuts.

Grain feeding is the usual nutritional regime adopted in lot-feeding, and this has the potential to create a number of **health** and **welfare** problems because the rumen is designed for a forage-based diet. Normally, the ruminal environment supports a population of protozoa and mainly Gram-negative bacteria, and these microbes convert carbohydrates to volatile fatty acids, carbon dioxide and methane. With readily fermentable carbohydrates, such as grains, there is a change to the fermentation pattern and microbe populations and total volatile fatty acids increase, resulting in conditions such as acidosis, ruminal distension (**bloat**), **laminitis** (**lameness**), systemic dehydration, rumenitis, liver abscesses and, in extreme cases, sudden **death**.

Rigorous nutritional management is required to avoid the deleterious conditions associated with feeding high-grain rations. A gradual introduction to grain will allow the ruminal microbes to adapt, and sudden changes in diet composition should always be avoided. Rations should start at about 60-70% roughage, with a gradual decrease in roughage and increase in grain over a 3-4-week period until the finishing ration, containing about 70-80% grain, is achieved. Most rations also contain antibiotics that act as ruminal modifiers and, depending upon the level of inclusion in the diet, will act to increase the efficiency of feed use and improve liveweight gain (growth promotants) or, at therapeutic levels, will have anti-acidosis and anti-bloat effects in order to minimize the problems associated with high-grain diets.

The size and dimensions of a feedlot yard or pen will depend upon the species, the number of animals in the group and the stocking rate (average space allocated to each animal (**see: Stocking density**)). Pen shape may affect access to feed; generally, pens are rectangular with feed available from a trough or

bunk on one long side, which maximizes feeding space and limits the distance that animals have to move to reach feed.

Many countries have standards or **codes of practice** that stipulate minimum space allowances for animals, not only for general space, but also for feeding and drinking space. Stocking rate is critical, as it impacts on the health, welfare and productivity of the animals. High stocking rates may result in social tension (**see: Social stress**) because individuals are unable to avoid or escape from each other and thereby terminate aggressive interactions (**see: Aggression**). It has been suggested by some workers that the '**buller-steer syndrome**' that occurs in feedlot cattle, in which a particular animal or animals is/are persistently mounted and ridden by group-mates, is associated with the establishment and maintenance of the social hierarchy. Other researchers believe that the syndrome may result from multiple stressors, one of which may be social dynamics associated with large group sizes (rather than space allocation per se). Hormonal status (natural variability and from hormonal growth promotant implants) has also been implicated in the syndrome.

Space restrictions may make it difficult for some animals to access resources such as a resting site, food and water. High stocking rates may also mean that contagious diseases are spread easily and rapidly through the group. Stocking rate can also affect animal health and welfare by its impact on the moisture content of the 'pad', or soil/excreta substrate. Pad moisture content determines the production of noxious gases (e.g. ammonia), odours and dust, which can lead to or exacerbate respiratory problems. Wet, boggy conditions can lead to **footrot**, foot lesions and lameness.

One disadvantage with feedlots is that they provide a relatively unstimulating environment for the animals, and oral **stereotypies** may be observed in animals that are in feedlots for extended periods (**see: Boredom**). These stereotypic behaviours are probably a result of frustration of the motivations associated with grazing, combined with the consequences for the animals' **time budgets** of the low levels of roughage in the diet (**see: Tongue-rolling**). Some workers have also suggested that the buller-steer syndrome may be related to an unstimulating environment.

Feedlots need to provide protection for the animals from climatic extremes. In cold climates it is essential to provide protection from winds and a dry area for the animals to rest. In tropical and subtropical climates there can be high mortalities through excessively high thermal loads (generally a

P.261

combination of high air temperature and high relative humidity) on the animals. The provision of shade is recommended, but the positioning and levels need careful consideration to avoid exacerbating **heat stress**. Animals may group tightly together under shade and actually reduce the opportunity for heat loss; and, following wet weather, shade delays the drying of the pad, which can raise relative humidity locally (thus adding to the heat load) and also create problems for foot health.

Feed restriction

Feed restriction is a type of management procedure in which the amount of feed the animal would consume to eliminate **hunger** sensations is limited by one of multiple mechanisms. Feed restriction is related to other types of management scenarios that induce hunger, i.e. qualitative dietary restriction, in which the animal consumes a full amount of a diet that is nutritionally inadequate due to an absent nutrient or other required component. Thus qualitative restriction provides for *ad libitum* consumption of an inadequate diet, whereas feed or *quantitative* dietary restriction provides a complete diet, though not enough to satiate the animal.

Feed restriction can be imposed either indirectly or directly in relation to the caretakers' provisions. In cases where feed is restricted indirectly, some aspect of the environment prevents the animal from consuming an adequate amount. For instance, animals on pasture, where considerable distance exists between foraging opportunities, are limited by the travel time between foraging sites. Even though unrestricted in their movement, animals are unable to meet their nutritional needs and may enter a state of negative energy balance.

In another example of indirect restriction, animals can be restricted from feeding by **conspecifics**. Livestock typically maintain similar daily routines for eating, drinking and sleeping activities. However, when access to the feed source is obstructed by herd-mates at the feeder, animals must adjust their feeding times accordingly. This will become a concern when low-ranking animals are not able to gain access to the feeder for long enough periods of time to ingest what would be their sufficient daily ration.

A variety of environmental conditions can induce changes in **feeding** behaviour, of which increased ambient temperature is the most severe. The process of food digestion releases heat as food particles are broken down into their basic components. Homeothermic animals, or animals that maintain body temperature by balancing heat loss and production, will normally dissipate heat produced from digestion to the surrounding environment. As ambient temperature rises, heat is less able to exit the body. If temperatures continue to rise, the animal acts as a sink and pulls in heat from the environment. In such situations, animals decrease intake to reduce heat produced from digestion and thereby maintain required body temperature. If temperatures are severe enough that these responses are ineffective, animals will exhibit decreases in weight gain - or even show weight loss - and eventually lower their overall metabolic rate.

Animals may experience feed restriction imposed directly by caretakers, typically for some production benefit. In this classification, animals are fed some amount of feed that is less than the amount consumed if allowed to feed *ad libitum*. Direct quantitative restriction is a common production regimen used in several livestock scenarios.

Restricted feeding for sows/gilts

Restricted feeding of gestating sows and gilts is a popular method to restrict weight gain and prevent obesity, improve feed efficiency, increase **lactation** yields and reduce feed costs. Modern swine production utilizes an animal that has comparatively reduced fat reserves and appetite compared with earlier generations of animals. Combined with an increased litter size, metabolic requirements have grown in spite of reduced endogenous energy reserves. These conditions typically force the sow/gilt into a catabolic state in which she is unable to satisfy her lactation demands and, as a consequence, will lose significant amounts of body fat and other essential tissues. Increasing intake during **gestation** to allow the sow to establish reserves during lactation is one method of correcting for such deficiencies; however, a restricted diet during gestation has been shown to be far more efficient and effective.

Salmon-Legagneur and Rerat (1962) reviewed theoretical work suggesting that increasing feed levels during lactation versus gestation was a more efficient means to deliver nutrients for lactation production versus endogenous reserves. These theoretical predictions were validated by weight gain and 16% greater milk production in sows that were fed restricted levels during gestation and overfed in lactation compared with a second treatment group receiving the reverse. Thus, increasing lactation intake should be the producers' primary goal. Interestingly, restricted feeding during gestation can serve to increase lactation intake. Sows receiving a restricted intake during gestation eat significantly larger quantities during lactation, the converse of which has proved true as well. Further advocating the benefit of such a regimen, animals receiving low feed amounts in gestation and high amounts in lactation consume less feed overall, suggesting a greater feed efficiency.

Interval feeding

Interval feeding is a technique used primarily in swine production to reduce labour requirements where animals have to be fed manually, although some improvements to feed efficiency have been found. In such systems, sows are fed a bulk amount once per interval where the interval may range up to 3 days. Animals receive the same amount of feed over the course of the interval: only its distribution within the interval is altered. Interestingly, Douglas *et al.* (1998) reported that sows on an interval feed schedule exhibited reduced behavioural signs of hunger, although such conclusions need further investigation before application.

Forced moulting

The technique of **forced moulting** used by the poultry industry provides a third specific example of feed restriction for production benefit. Forced or induced moulting is practised by poultry producers to rejuvenate layers in their operation. The practice typically involves all or a combination of: feed removal for 4-14 days; water removal for 1-3 days; and a decrease in light exposure to 6-10 h/day. Adoption of these practices is believed by some to mimic a natural biological process of poultry that occurs as a result of seasonal decreases in food availability and daylight exposure. Such conditions will

P.262

reduce or eliminate gonadotropic support of the hen's ovary via decreased release of **gonadotropin-releasing hormone (GnRH)**. Forced moulting has been shown to increase egg production by approximately 10% over non-moulted birds. Egg quality has also been shown to improve as well.

Broiler breeders

Genetic selection for rapid growth rates and high feed intake has resulted in broiler chickens that reach **slaughter** weight at 7 weeks of age. The rapid growth rate results in welfare issues associated with **bone strength** and organ growth. It also has consequences for the breeding flock, where egg laying does not start until around 24-26 weeks of age. In order for broiler breeders to reach reproductive age, feed restriction has to be practised to prevent obesity and to control **growth rate**.

Overall, the practice of feed restriction, though necessary in production systems that need to control weight gain of breeding animals and birds, may result in chronic hunger of individuals. Feed restriction therefore may have large negative welfare consequences for affected individuals.

Feelings

Feelings, such as love and happiness, are defined as conscious emotional states generated by physiological and/or psychological processes that may in turn be triggered by sensory perceptions (e.g. visual or tactile) or memories. Scientists have traditionally stressed the importance of **consciousness** when trying to distinguish between feelings and other emotional expressions. This has resulted in the frequent association between emotions and instinctive responses on the one side and feelings, a **theory of mind** and abstract thinking on the other. Recent advances in animal **cognition** seem to suggest that some non-anthropoid species may be able to experience some sort of human-like feelings. Moreover, some scientists disagree with the view that feelings have to have a conscious basis and prefer a 'loose' definition of the term to include unconscious emotional states. These considerations have led some scientists to propose that the use of anthropoid primates, and possibly of other species too, for animal experimentation and their housing in zoos and laboratories should be banned.

Feminist ethics

Feminist ethics takes as a starting point a critique of the dominant traditions within ethical theory for having a sexist, male bias. Feminists are concerned with creating gender-equal moral principles, policies and practices, and supplementing masculine ways of moral reasoning by giving prominence to women's experiences. Varieties include maternal and feminine **ethics**. In the case of animal ethics, one popular strand is the ethics of care. Mary Midgley, for example, contends that our responsibilities towards animals are a function of the relationships or community we form with them. The greater our sense of community with certain animals, e.g. **pets** and farm creatures, the greater our sense of responsibility.

(RA)

Fence-line behaviour

Fences serve as physical, visual and/or psychological barriers to keep animals within or outside a particular area. Factors that keep animals from penetrating a fence-like barrier are rooted in the physical properties of the fence (i.e. height, porosity, horizontal or vertical spacing within the fence, sharp barbs, voltage, etc.) and the cognitive realization by the animal that it cannot pass through, go over or go under without consequences (i.e. by being physically stuck, receiving an electric shock, jabbing by sharp barbs, etc.). Many farm species learn, with relatively few trials, and often only one trial, to recognize the

properties of a fence that allow them to penetrate or be repelled by a particular fence and they are able to associate and apply that knowledge to other locations where they find similar barriers with similar visual cues. However, future invisible or virtual fences may operate by guiding animals via auditory cues or vibrations from their **collars** or ear tags to avoid delivery of an electric shock (Butler *et al.*, 2006).

Motivational changes, such as **hunger**, **fear** or isolation will cause animals to try to breach fences that they would normally respect, which explains why fences in more intensive systems or near handling facilities are more formidable in construction. Ruminants also appear to have some awareness of fences acting as a barrier or as protection, separating them from individuals on the opposite side. For example, the normal flight zone that a ruminant would display between a predator, a human or another more dominant **conspecific** is physically reduced when a fence separates the two individuals. Likewise, separating a dam and her suckling offspring, on opposite sides of a fence, will elicit overt signs of **distress** (i.e. increased **vocalizations** and pacing) despite the fact the individuals may only be separated by a few centimetres (see Fig. F.4). However, fence-line **weaning** offers a better alternative, causing fewer overall signs of distress, compared with weaning by abrupt and remote separation of mother and offspring (Price *et al.*, 2003).

P.263

Feral

An individual or population of domesticated animals that is no longer living in **captivity** may be referred to as being feral. Such animals have reverted to a wild or semi-wild state, with little or no dependence on humans. Feralization describes the process by which a domestic animal becomes feral, and may involve selection within this non-captive environment. Changes that occur include an increase in their flight distance from humans and possibly the formation of social bonds with other feral **conspecifics**. Feral species may have an important impact on the **ecology** of the areas in which they live, e.g. feral cats can eliminate local wildlife where such a predator does not naturally exist.

(KT)

Ferret

A ferret is a small carnivorous mammal of the weasel family. It is similar to a weasel but has longer fur (known and sold as fitch). Ferrets are domesticated strains of the polecat developed for **hunting game animals**, particularly **rabbits**. Polecats grow to nearly 60 cm long, including the tail. The fur of polecats is dark brown above, with yellow patches on the ears and face, whereas the ventral surfaces are nearly

black. Their scent glands, located either side of the anus, emit a powerful fetid odour. It has been used for research into influenza in humans, as it is one of the few animals that develop the disease.

(DBM)

Fetus (foetus)

A stage in prenatal development when the organs become recognizable. At this point the developing **embryo** is known as a fetus, and the remainder of the **gestation** involves mainly fetal growth rather than organ development.

(DBM)

Field study

Any study carried out in the 'field', which in its broadest sense is a location where the animals under study can move about at will and potentially interact with members of their own and/or other species. A classic field study does not involve any manipulation of the situation. This does not mean, however, that hypotheses cannot be tested; for example, behaviour could be compared between different existing situations or populations. It is also possible to undertake experimental field studies, in which the classic experimental method of variable manipulation is applied.

Fish welfare

Although some of the earliest animal welfare legislation, the United Kingdom Protection of Animals Act (1911), specifically covered fish as well as birds and other domestic animals, public concern and scientific interest in the welfare of fish has notably lagged behind that of the terrestrial animals affected by man. This was probably primarily because of a lack of empathy and understanding of a species adapted to a natural environment so very different from our own. However, there is a recent, growing interest in potential welfare issues, as research brings to light the true complexity of fish and the mechanisms with which they are equipped to adapt physiologically and behaviourally to survive.

The term 'fish' covers a wide range of animals. Most scientific work has been carried out on teleost fish (bony, rayfined fish) and, in terms of the number of species and biomass, teleosts are the typical vertebrates and also those most used by man. This article is primarily concerned with the welfare of teleost fish. An exhaustive discussion of the concept of fish welfare and the issues surrounding fish welfare can be found in Huntingford *et al.* (2006) and others (see References and further reading).

The concept of 'fish welfare' is perhaps only relevant in terms of the consequences to the fish of actions by man. Human activities that affect fish welfare include our effect on the fish environment and, although this is rarely noted, it is our effect on the environment as a whole, through pollution and other

disturbances to the ecosystem, including loss and modification of habitat, that may degrade the welfare of the greatest number of individual fish.

Commercial fishing and sport fishing present many potential welfare problems. The process of capture from the wild is likely to be stressful and, in many cases, involves a prolonged death, as fish may be subject to injury, dramatic change of pressure, exhaustion, oxygen deficit, crowding and dragging in nets. Once landed there is generally an urgency to process a catch. Fish flesh deteriorates much more rapidly than that of warm-blooded animals, as the enzymes of cold-blooded animals continue to function efficiently after death. The enzymes of warm-blooded animals work less efficiently as the body changes temperature, cooling post-mortem. The requirement to keep fish very fresh up to the point of consumption often leads to a compromise of their welfare, with fish being transported live and even served prepared, but alive and conscious, as may be experienced in some sushi restaurants. In

P.264

the case of commercial sea fishing, the fish are not humanely killed as is required in most land-based **slaughterhouses** processing domesticated animals. While alive and conscious, fish may be eviscerated, packed in ice and otherwise processed. Demersal fish (bottom feeders), in particular, have been shown to take up to 40 min or more to die following evisceration and packing in ice (Robb and Kestin, 2002).

Besides commercial fishing, the scale of sport fishing should not be underestimated. For example, the 2006 National Survey of Fishing, Hunting and Wildlife-Associated Recreation (US Census Bureau, 2006) shows that in the USA there are 30 million anglers (approximately 13% of the population) spending US\$42.2 billion on their sport each year. In part due to depletion in fish stocks from overfishing, there has been a dramatic increase in aquaculture, producing fish for the table. Within Europe, aquaculture has been the fastest growing animal production sector, with an increase in both the number of species farmed and the total amount of fish produced. Farmed fish in Europe alone now include such diverse species as carp, salmon, trout, tilapia, catfish, sea bream, sea bass, eel, turbot, halibut, barramundi and cod. The farming of each new species requires the development of specialized knowledge and associated techniques if potential welfare problems are to be avoided. For example, mistakes in water quality, temperature or feeding when rearing from eggs through larval stages can lead to deformity and **abnormality** of almost all the fish in batches containing hundreds of thousands of animals. Fish may be reared at high stocking densities under highly constrained conditions, affecting their ability to carry out normal behaviours such as feeding, shoaling and **predation/parasite** avoidance. Factors such as these are thought to be the reason why the majority of farmed salmon and trout suffer high levels of fin erosion and why injuries, especially of the eyes, are more prevalent than in wild populations.

Other potential welfare problems in aquaculture include increased exposure to disease, poor water quality and the effects of husbandry procedures such as handling, grading, **transport** and harvest. The majority of fish are not stunned after harvest and death can be prolonged. Many fish are allowed to asphyxiate, often on ice or in an ice slurry. Salmon are frequently exsanguinated by gill cutting, a method which leads to death only after several minutes. A full review of **slaughter** methods is given in Robb and Kestin (2002), in which the majority of methods are found to be unsatisfactory. Electric stun/kill of fish at harvest has been shown to be effective, and methods are beginning to be developed for a range of farmed species and to be adopted by industry, often with support and encouragement from large buyers such as the supermarkets (see, for example, Lines *et al.*, 2003).

Fish are used in scientific research and for toxicity testing of products and of, for example, water supplies. Of the 3.2 million scientific procedures licensed to be carried out within the UK, 10% were carried out on fish (Home Office, 2008). Fish in research may be subjected to deliberately imposed treatments that may have a variety of adverse effects on growth, behaviour and physiology. Fish are also kept for private and public display. Ornamental fish are often captured from the wild using sublethal doses of poison and may undergo extensive transport. In captivity, as in aquaculture, their care depends

on owners providing an appropriate environment. It is not uncommon to find predator and prey species kept within the same enclosure, a practice generally frowned upon in, for example, a terrestrial **zoo**.

Potential welfare problems exist only if fish have the ability to suffer. At present the evidence either way is not entirely satisfactory. Rose (2002) puts forward a strong argument that fish are unable to 'experience' **pain** and are unable to suffer, stating 'the reactions of fishes to noxious stimuli are nociceptive and without conscious awareness of pain'. His argument is in the main part based upon a comparison between the neural structures present in fish and those present in mammals, with particular reference to man. An alternative view is summarized in Huntingford *et al.* (2006), which they relate only to adult fish. They draw on the current literature showing that, of those investigated so far, several fish species are capable of learning and integrating information and that this requires processes more complex than simple associative learning. Based on this evidence and supposition they state that 'where there is evidence of fish species with sophisticated cognitive and behavioural processes, the experience of suffering may be a real possibility'. A strong piece of work in support of Huntingford *et al.* (2006) by Sneddon *et al.* (2003) found that when rainbow trout were administered bee sting venom around the mouth they suspended feeding, showed a greatly increased rate of opercular beat and moved to the bottom of the tank to rock gently from side to side. Current research in this area is turning to functional and structural magnetic resonance imaging (MRI) techniques to help investigate **brain** functioning and remodelling during **aversive** episodes. Whatever the eventual outcome of the argument, for the time being it is suggested that the 'precautionary principle' is adopted.

P.265

Fission-fusion social system

This is a type of social grouping in which all individuals belong to a parent group that can fracture (fission) into smaller stable subgroups or individuals to seek out dispersed resources, such as forages or mates, but afterwards return to the larger parent group (fusion), often using contact calls to facilitate this reunion. There can be fluid movement of individuals between subgroups and even between different parent groups, such that group composition and size are frequently changing. In order for a **social group** to be spatially coherent, its members need to synchronize their activities. However, synchronization can be costly to individuals if it causes them to put off an activity that would benefit them more than what the group is doing. This will occur more in groups comprised of different ages, sexes and sizes, since optimal time allocation is likely to differ between these individuals. Thus, division into smaller subgroups can facilitate **synchronization of behaviour** in individuals with similar requirements. Species that have a fission-fusion social system tend to have very large brains relative to their body size, suggesting that this type of system may be cognitively demanding (**see: Intelligence - comparative**), perhaps relating to the difficulty of managing social relationships with individuals which are out of contact for long periods of time.

(LMD)

Fitness

In evolution, success is defined by the persistence of genes in a population. There are three ways to do so and, together, they define an individual's inclusive fitness. First, survival and doing things that help an individual survive maximize personal fitness. Secondly, **reproduction** and doing things that help an individual reproduce maximize direct fitness. Thirdly, helping relatives survive and reproduce, since kin share common genes (**see: Kinship**), maximizes indirect fitness.

(DTB)

Five freedoms

The basis for the five freedoms was first documented in the **Brambell Report** in 1965, but not formalized as such until later. They comprise:

- Freedom from thirst, **hunger** and **malnutrition** (by ready access to fresh water and a diet to maintain full **health** and vigour).
- Freedom from physical and thermal discomfort (by providing an appropriate environment including shelter and a comfortable resting area).

- Freedom from **pain, injury and disease** (by prevention or rapid diagnosis and treatment).
- Freedom to express most patterns of normal behaviour (by providing sufficient space, proper facilities and company of the animal's own kind).
- Freedom from **fear and distress** (by ensuring conditions and treatments that avoid mental **suffering**).

Flehmen

The term flehmen was introduced by Schneider in 1930 and refers to a conspicuous behaviour performed by ungulates and members of many other taxa in response to **pheromones** from other animals, usually **conspecifics**, but also other species. Pheromone is the term used for a chemical that transmits messages between animals. The flehmen response involves a characteristic **posture**: the animal stands erect, extends its neck, raises its head, flares the nostrils, opens its mouth slightly and curls the upper lip, often exposing the upper gum (performs a 'grimace'; see Fig. F.5).

Flehmen is generally performed in response to the smelling and/or licking of **urine** and/or the anogenital region of another animal. It is often performed repeatedly to the same stimulus and may be maintained for a minute or more. The behaviour is thought to facilitate the transport of relatively non-volatile compounds to the **vomeronasal** (or Jacobson's) **organ**, which is a chemoreceptor organ located in the vomer bone between the nasal passages and the mouth. Thus the vomeronasal organ appears to be used for the perception and analysis of pheromones, allowing the animal performing flehmen to gain information about the animal emitting the pheromones.

Generally, flehmen is performed by a male to the urine of a female, is often seen in a sexual context and, thus, one function of flehmen may be to allow a male to determine the reproductive status of a female. However, this cannot be the only function, as it occurs interspecifically, and in some species it is performed during female-female and male-male encounters. There are also reports that, in some species, females perform flehmen to neonates and amniotic fluid. Thus it may be that

P.266

flehmen is used for individual **recognition**, as in offspring recognition by mothers, and recognition of certain attributes of an individual, such as social status, which may be revealed through hormonal levels.

Flight behaviour

To help grazing animals avoid predators, they have wide-angle or 360° panoramic vision. This enables them to continually scan for predators while they are **grazing**. The principles of flight behaviours are similar in **horses, cattle, sheep, deer**, antelope and other grazing animals. To facilitate scanning for danger during grazing, the retina has a horizontal band with a high density of sensitive cells called the visual streak. Grazing animals are dichromats, which are partially colour blind, and their retinas are most sensitive to the colours yellowish-green and bluish-purple. Dichromatic vision may provide better vision at night and make detection of motion easier.

Sudden movement is very stimulating to the nervous system. Research by Joseph LeDoux indicates that sudden movement stimulates the amygdala, which is that part of the **brain** that controls **fear** responses. This results in the grazing animal taking action against the danger. Small, fine-boned grazing animals, such as antelope, avoid predators by fleeing, but animals such as cattle, with heavier bones and bodies, will also turn and fight a predator instead of running. It has been found that those cattle most likely to become agitated in an auction ring and ram the fence were those that were also most likely to flinch and jump in response to the waving of the auctioneer's hand when he took a bid. The animals with the flighty **temperament** were the most sensitive to rapid movement (Lanier and Grandin, 2000).

A novel sudden movement is more likely to elicit flight behaviour compared with a familiar one. For example, Nyala antelope in a zoo have little fear of children running by the fence outside their exhibit, but the novelty of people moving around on the roof of a building within the enclosure can provoke an intense flight reaction and the animals may run into the fence. In the life of a grazing animal, new things are both **aversive** and attractive. This is the paradoxical effect of novelty. Cattle may baulk and refuse to move if they are driven by people towards a novel strange flag, but that same flag will attract the cattle and cause them to approach if placed in the middle of their pasture. Novelty is aversive when it is suddenly introduced and attractive when the animal can voluntarily approach it (**see: Approach test**).

Flight zone size and principle

The size of the **flight zone** is the distance an animal will allow a person to approach before it moves away. The artificial removal of the flight zone is the process of **taming** (Hedigar, 1968). Tame animals will allow themselves to be touched and handled. Other factors affecting the size of the flight zone include genetics and whether the animals have become agitated. Herds of cattle that have been handled quietly will have a smaller flight zone compared with herds that have been handled roughly by people who yell, scream and hit them. The size of an object will also affect the size of the flight zone: when a person approaches full face, the flight zone will often be larger than when approaching with a smaller sideways profile.

The design of handling facilities can reduce the size of the flight zone. The size of the flight zone diminishes if there is a solid fence that blocks vision between a person and the animal. Solid sides help to prevent dangerous flight behaviour when wild, untamed grazing animals are handled. Blindfolding an animal with completely opaque material can also help to maintain calm.

The use of solid sides is most important when animals with a large flight zone are handled (**see also: Restraint**). Solid sides should be installed on restraint devices, single-file races, truck loading ramps and the crowd pen that leads up to the single-file race. When completely tame animals are handled, such as a tame draught water **buffalo** that is trained to lead or a completely tame dairy cow, solid sides are not needed. However, a water buffalo that has become **feral** and allowed to run wild will have a large flight zone and solid sides will be a necessity. Grazing animals are controlled by vision. A flimsy solid fence made of thin opaque plastic or cloth may hold them in because they will not run through a solid barrier. Groups of animals can be moved by people holding a long strip of plastic. A solid top on a single-file race or a **restraint** device will inhibit rearing. Wild horses, bison and other animals will often rear up when a person gets too close. A piece of cardboard or other solid material placed over the top of the race will often stop rearing.

Handling principles

Cattle can be moved most efficiently if the handler works on the edge of the flight zone. The animals move away when the flight zone is penetrated and stop when the handler retreats. The edge of the flight zone is not distinct or set, and approaching an animal quickly will enlarge the flight zone. Excited cattle have a larger flight zone, and eye contact with the animal will also enlarge the flight zone.

To make an animal go forward, the handler should stand in the shaded area marked A and B in Fig. F.6. The handler must stay out of the blind spot right behind the animal's rear. At close quarters, a handler is likely to get kicked if he/she enters the blind spot. In pastures, entering the blind spot will cause the animal to turn and look at the handler; the animal does this to determine where the handler is. To make an animal move forward, the handler must remain behind the point of balance at the shoulder (see Fig. F.6). To make the animal move backwards, the handler should be positioned in front of the point of balance. Handlers should avoid standing in front of the point of balance when they want to make an animal move forward.

Use of the movement patterns shown in Fig. F.7 will induce cattle and other grazing animals to move forward in a race. The animal will move forward when the handler walks past the point of balance in the opposite direction of desired movement. The handler can turn cattle in a small pen by using a flag on a stick to block the animal's vision on one side. Moving the flag towards the right side of the animal's head will make it turn left. When an animal is faced head on it will turn right if the handler moves left and vice versa.

Survival behaviour pattern

Grazing animals have two basic survival behaviour patterns relating to flight. They are: (i) turn and face a potentially

P.267

threatening stimulus but keep a safe distance (flight zone); and (ii) use the point of balance (Grandin, 2000). Turning and looking at potential danger enables the animal to know where a potential predator is. A distant predator that can be seen is not going to eat them. Grazing animals appear to detect whether or not the predator is looking at them. A lion that is looking at them is a greater threat to them than a lion passing through. Point of balance helps a grazing animal get away from a chasing predator. This appears to be a hard-wired behaviour that helps the animal evade capture.

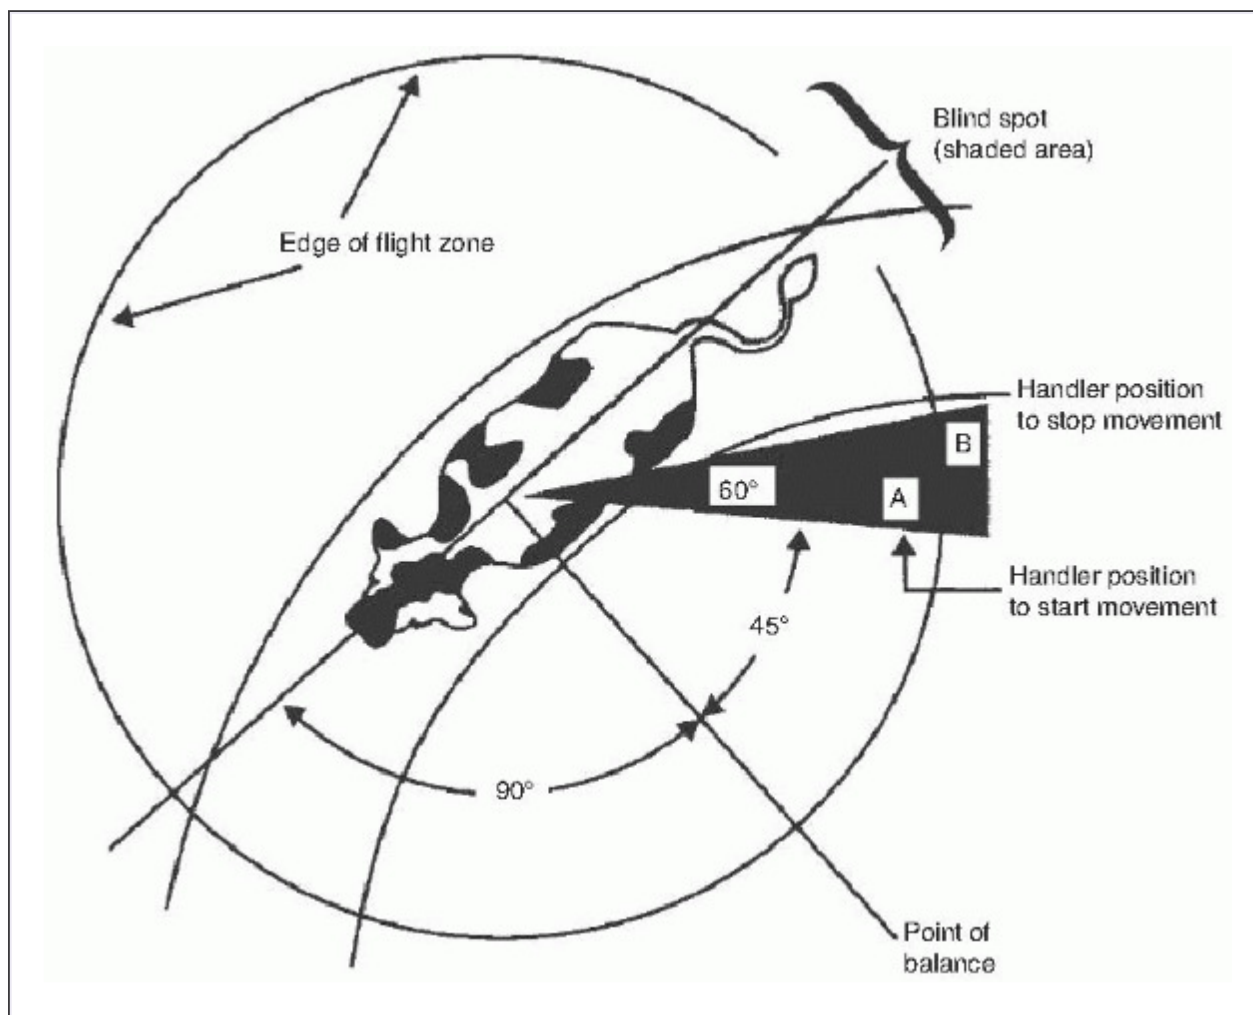

Fig. F.6. Flight zone diagram showing the most effective handler positions for moving an animal forward.

Fig. F.7. Handler movements to induce cattle to move forward in a race.

Depending upon the species of grazing animal, the strategy for protection from predators varies from pure flight to turn

P.268

and fight. Antelopes and horses are more flighty and survive by fleeing. Cattle use both fleeing and turning on a predator and attacking, and the cape buffalo attacks. Other grazing animals stay together in larger herds to provide safety in numbers. When the herd is threatened, the animals bunch together.

Flight zone

The flight zone is the area around an individual that it actively attempts to keep free from interference from other animals or objects. Intrusion within the flight zone elicits an escape response. The distance from an animal's head to the edge of the flight zone is known as the flight (initiation) distance. The size of the flight zone is thought to be determined by an animal's genetics, sex, age, body size, **health**, reproductive condition, **temperament** and its perception of the threat. The amount of contact with other animals and the quality of that contact will also affect the length of the flight distance, with **wild animals** typically having a much larger flight zone than their domesticated counterparts (**see: Domestication**). Habitat type and the distance of travel required to reach a refuge can influence flight distance, as can the speed, agility and behaviour of the encroaching animal and the direction from which it is advancing. **Cattle**, for example, will have a larger flight zone when approached from the front than from the side or back. For arboreal species, the horizontal, vertical and diagonal position of the approaching animal can influence the length of their flight distance.

Understanding the flight zone is important when **handling** animals. Handlers working on the edge of a flight zone are able to control an animal's movement by approaching and withdrawing from the animal. However, penetrating the flight zone too deeply may cause the animals to flee. Conversely, a handler standing outside an animal's flight zone may have difficulty getting that animal to move. Sufficient handling and human socialization can decrease an animal's flight zone to the point where the flight zone may disappear. Animals with no flight zone can be difficult to handle and, on occasions, aggressive towards humans.

Flocking behaviour

Flocking behaviour is shown by many gregarious species, but particularly refers to when a group of **sheep** or birds cluster together. Many sheep breeds exhibit this behaviour, which originated from a response to the presence of a perceived predator. It arises from the advantage of having a greater number of eyes looking out for predators, which increases the chances of their detection (**see: Vigilance**). **Grazing** can occur in relative safety when many individuals are keeping watch. As a consequence dietary intake is increased as more time can be spent grazing rather than on the lookout for predators. In areas where no natural predators exist for the species, such as Iceland for sheep, the local breeds of sheep show little flocking behaviour.

Flocking behaviour is a useful trait for many farmers, as a large, compact group of stock is much easier to handle and move than a fragmented set of individuals. The sheep exhibit this behaviour because they perceive the humans and any working **dogs** to be threats, and thus cluster together. However, the behaviour can give rise to problems in situations where feed is limited. Overgrazing of highly palatable

areas will occur readily, which leads to environmental damage and **welfare** problems of **malnutrition** and, in extreme cases, **starvation**.

Connected to flocking behaviour is hefting - where sheep naturally graze around the areas in which they were born and grazed as lambs within the flock. This behaviour is highly beneficial for shepherds on open mountain land, as it negates the need for expensive walls or fences (often on land on which they may be difficult to construct). In combination with flocking behaviour, these two interlocking behavioural traits give the shepherd an advantage when managing the stock.

(MM, HO)

Flooding

When an animal experiences a **stimulus** that evokes an emotional response such as **fear**, a behavioural response is elicited, which may be associated causally or coincidentally with the removal of the initial stimulus. As a consequence, the response will be reinforced and thus it is likely to be repeated at future exposures. Also, if a non-significant but arousing stimulus is removed before **habituation** occurs, the converse process, **sensitization**, may result. Such responses may form the basis of problem behaviours, as they can be difficult to eliminate if the animal is never given an opportunity to experience the stimulus and learn to tolerate or exhibit an alternative, more desirable response. One of the behaviour modification techniques that can be employed to change such responses, if they are inconsistent with the level of threat posed by the stimulus, is flooding.

Flooding (also referred to as response prevention) involves exposing the animal to the stimulus, while preventing it from escaping or avoiding the stimulus, until the negative response that is exhibited ceases. The aim of the procedure is to enable the animal to either habituate or learn an alternative appropriate response to the stimulus, through the removal of reinforcement for the behaviour (**extinction** of the learned response).

The stimulus can be presented at full strength from the earliest exposure or, alternatively, graded exposures to everincreasing strengths can be presented. For elimination of the response to occur it is important that the stimulus is not withdrawn before cessation of the response occurs, because if the animal still remains in a state of heightened **arousal** and

P.269

the stimulus is withdrawn, the response may be negatively reinforced (**see: Reinforcement - types of**) and hence strengthened, or sensitization may occur as a result of the heightened arousal experienced. Such incorrect implementation of flooding is one of the significant risks of the procedure.

Alternatively, an inadequate time lapse between exposures that does not allow complete physiological and behavioural abolition of arousal before the next exposure may lead to a similar outcome. Another cause for concern is that, if the animal is being restrained and exposed to uncontrollable **aversion**, **learned helplessness** may result. In this case the animal will be passive, and may superficially appear to have improved, but its welfare is seriously compromised. Even if the animal is not experiencing **distress** due to the stimulus (e.g. it is being used by an animal that gets overexcited), it will be subjected to **frustration** if the response has been previously reinforced, and this in itself can be highly aversive and seriously compromise the animal's welfare. Therefore, flooding should only be used as a clinical tool for behaviour modification with caution, after the rejection of other alternative methods of eliminating the behaviour (e.g. **systematic desensitization** and **counter-conditioning**), and only following a careful assessment of all aspects of the welfare and safety for all people and animals involved in the procedure.

Flooring

The floor is the point of intimate contact between animals and their **housing**. The type of flooring used in the housing affects the **welfare** of the animals in a number of ways. Use of hard or uncomfortable flooring surfaces in the areas where animals rest or **sleep** can substantially reduce the amount of time that the animals lie down. This is particularly true for large animals such as adult cattle or pigs. The precise effect of this on animal welfare is hard to determine, but adequate sleep and rest are clearly essential for the welfare of most animals (**see: Resting behaviour**). Furthermore, research on dairy cows suggests that a reduction in lying time, if sufficiently large, can increase the incidence of **lameness**.

Most research on resting surfaces has used lactating dairy cattle, and one firm conclusion is that cubicles for dairy cows should not have bare concrete floors, which have been found to reduce resting time by up to 20%. This is associated with an increased incidence of swollen (front) knee joints that comes about because cows initially put their weight on their front knees when both lying down and standing up. The swelling in the knees makes both standing up and lying down difficult, with the result that, when cows must lie down on hard floors, they spend more time standing and lie down less often.

Preference tests have shown that, in general, cattle, horses, sheep and pigs prefer to lie on well-bedded surfaces, e.g. deep straw. Straw bedding can provide the means for pigs to express their rooting behaviour. Growing pigs raised on straw show less nibbling and rooting at pen fixtures and pen-mates than those raised on bare floors. However, concern about bacterial or other contamination (for example, leading to increased **mastitis** in lactating cows or foot-pad dermatitis in broiler chickens) has led farmers to reduce their use of organic bedding. Sometimes this results in animals having to lie on bare concrete floors, although in the dairy industry, particularly, there is much interest in alternatives such as sand, mats or mattresses (or even waterbeds). It is essential for the welfare of dairy cows that floors be sufficiently soft.

The type of flooring used in lying areas can also be important for **thermoregulation**. Thermoregulatory requirements of animals will vary with the age of the animal, the type of production and the climatic area in which the animals are kept. Evidence for the importance of thermoregulatory function in floors is that shorn sheep prefer deep straw bedding over bare floors, but this preference is less obvious in unshorn sheep. Growing pigs prefer deep straw bedding at colder temperatures, but prefer bare concrete floors at high temperatures. Young calves, lambs and piglets are most likely to suffer from hypothermia, and so require warm, well-insulated lying surfaces. In contrast, high-producing dairy cows in peak **lactation** and older milk-fed veal calves generate considerable metabolic heat and tend to suffer more from **heat stress** than **cold stress**. Their prime thermoregulatory requirements are, therefore, for losing body heat. Heat stress can be a particular problem for beef cattle in many of the hotter parts of the world. For example, heatwaves are a common occurrence in the southwestern states of the USA, and thousands of cattle have been known to die as a result. Lying down on a cool, highly conductive surface can aid the animals in

losing heat. Wetting the ground in beef **feedlots** has been shown to help the animals to cope with high temperatures.

The type of flooring in areas where the animals walk or stand is important for animal welfare, since poor flooring choices can lead animals to slip (leading to injury) or can directly injure the animals' hooves or feet. To avoid slipping, floors need to have sufficient traction. Floors become slippery when wet or covered with **urine** and manure, and smooth surfaces - such as smooth concrete - should be avoided. Surface friction can be increased by adding some texture to the surface, for example by grooving the concrete. This is preferable to smooth concrete but there are still problems with the hardness of concrete. Softer floors provide more traction than harder floors, since the hooves sink into the floor. Cattle prefer to stand on softer surfaces than concrete, and the increased forces on the hoof when cattle walk on concrete increase the risk of physical **injury** to the hoof. The use of concrete floors in cattle houses has been implicated as a risk factor for increased lameness in dairy cows. Some dairy farmers cover the areas where cattle walk with special rubber mats, which are soft but have high surface friction. This increases the speed at which the cows walk and reduces the chance of slipping. Using softer flooring where cows walk and stand can reduce the amount of time the cows spend standing in their stalls, while softer floors in front of feed bunks may increase the time spent feeding.

Good drainage is essential in ensuring that floors are dry. Wet floors increase the chance of slipping but also result in the

P.270

hooves of cattle, sheep and pigs becoming softer. The hooves of cattle absorb water rapidly and become soft as a result. Increased softness increases the chance of hoof lesions. Wet floors, especially floors covered with slurry, harbour bacteria, thereby increasing the risk of transmission of infectious diseases. Wet floors have been implicated as a risk factor in dermatitis in dairy cows and, in beef feedlots or **lairage** facilities, have been found to have large bacterial counts.

Slatted floors, in which solid slats are separated by gaps or 'slots', are commonly found in indoor housing for pigs, beef and veal cattle, and in some indoor dairy barns. Generally, these are made of concrete, but wooden slats are also used, especially in veal production. These have some advantages in that they allow urine to flow through so that floors remain drier. Cows housed on slatted floors tend to have drier, harder feet. Slaughter pigs kept on partly slatted floors show less evidence of *Salmonella* infection than those on solid floors. The extent to which faeces is also removed depends on the relative size of the slats and slots and on the amount of animal traffic. Often, the performance of slatted floors in removing faeces is disappointing. Furthermore, poorly designed slatted floors can interfere with normal locomotion of the animals and can increase the risk of physical injury to the hoof, especially if slots are too wide or the slats have rough edges. Slatted floors are a risk factor for **tail tip necrosis** in indoor-housed beef cattle. Another major problem with slatted floors is poor air quality in barns, due to high **stocking density** and inadequate ventilation.

Fluctuating asymmetry

Symmetry in body form, particularly bilateral symmetry, is a widespread trait among animals. However, perfect symmetry rarely, if ever, exists. Typically, individuals with bilateral symmetry exhibit some small differences from an exact mirror image on both sides. These random, small deviations from perfect symmetry are termed fluctuating asymmetry.

By definition, calculations of fluctuating asymmetry are obtained by measuring the same morphological trait on each symmetrical side (e.g. the size of the left and right ears on an animal). This yields a signed value which, when measured over many individuals, should have a unimodal distribution with a mean of zero. In fact, the distribution of deviations is used as a defining characteristic to distinguish fluctuating asymmetry from other types of asymmetry such as directional asymmetry or antisymmetry.

While the exact mechanism generating these small random deviations is largely unknown, fluctuating asymmetry is thought to be a measure of developmental instability. The phenotypic expression of a trait is determined by both internal and external factors. Given one's **genotype** and environmental conditions, the left and right characters in an organism with bilateral symmetry should develop identically. However, the developmental pathway is subject to small, random errors that can create disturbances to cellular growth. This developmental noise can produce small, random variation from perfect symmetry. The likelihood of developmental noise resulting in fluctuating asymmetry depends on an organism's capacity to normalize and control variance in cellular growth despite perturbations. Developmental stability thus acts to reduce morphological differences, minimizing fluctuating asymmetry. Conversely, developmental instability reflects an individual's sensitivity to developmental noise, evidenced by the phenotypic expression of these stochastic processes that create fluctuating asymmetry.

The degree of developmental instability of an organism is influenced by the interaction between its genetic composition and environment. Environmental and genetic stressors, such as unfavourable environmental conditions, food limitations, toxins, **parasites**, **inbreeding**, **mutations** and hybridization, can tend to increase developmental instability. Because of the genetic basis of developmental instability, fluctuating asymmetry may play a role in **individual fitness**. In general, individuals with greater asymmetry have lower reproductive success and/or reduced survivorship. This relationship may be due to the allocation of energy needed during development. Animals developing under suboptimal conditions may be more susceptible to developmental noise because less energy is available for the metabolic mechanisms that control developmental stability. Furthermore, animals in suboptimal conditions need to allocate more energy for basal metabolism than for growth or **reproduction**. This in turn results in reduced **fitness**.

For example, western fence lizards (*Sceloporus occidentalis*) were found to have a higher degree of fluctuating asymmetry at sites that were designated for off-road vehicle use; while this observational study was only able to demonstrate a correlation between sites with off-road vehicle use and fluctuating

asymmetry, it may indicate a potential effect of added environmental **stress**. Similarly, parasites can place a considerable drain on their host's energy budget, which can negatively affect the development of their host. In fact, parasitism has been shown to be positively correlated with fluctuating asymmetry. More asymmetrical individuals also may be more at risk to **predation** or less able to compete. In one study observing the interactions of gemsbok (*Oryx gazella*) at waterholes, females with asymmetrical horns tended to be subdominant. Morphological asymmetry, particularly in traits that affect mobility, may make it more difficult for individuals to escape predation and therefore become easier prey items. For instance, a comparison of fluctuating asymmetry among prey items consumed showed that birds consumed domestic flies (*Musca domestica*) with asymmetrical wings and tibia more frequently than those that were more symmetrical.

Fluctuating asymmetry may also be an important factor in **sexual selection**, in terms of competition for mates or **mate**

P.271

choice. Significant negative relationships between fluctuating asymmetry and mating success have been found. For example, barn swallows (*Hirundo rustica*) were found to have lower fecundity when their tail feathers were experimentally manipulated to be more asymmetrical. This negative relationship may be more profound in males because, in many species, females tend to be choosier regarding mate selection and males tend to engage in more contest competition for access to mates. Due to the force of sexual selection, the negative effect of fluctuating asymmetry on mating success is also stronger when it involves secondary sexual characteristics. While potentially increasing mate attractiveness or competitive ability, elaborate sexual ornaments can be energetically costly and more susceptible to environmental variation. Thus fluctuating asymmetry in secondary sexual traits may reflect the genetic quality of the individual as well as the degree of environmental stress that the individual experienced during development. Both mechanisms can produce a negative relationship between size of sexual traits and fluctuating asymmetry.

Genetic factors may also influence the prevalence of fluctuating asymmetry. Using both wild and inbred lines of fruit flies (*Drosophila* spp.), the distribution of fluctuating asymmetry was shown to be directly related to the genetic differences between individuals and their level of developmental stability. The breakdown of genetic co-adaptations, as seen in hybridization studies on fruit flies and ninespine stickleback fish (*Pungitius* spp.), can lead to increased developmental instability. In addition, mutations or chromosomal abnormalities can create morphological asymmetries.

However, the relationship between fluctuating asymmetry and fitness is complicated by many confounding variables. For instance, the **heritability** of fluctuating asymmetry appears to be somewhat low. Furthermore, increasing environmental variance of phenotypic traits can also affect their heritability. Patterns between fluctuating asymmetry and fitness may be obscured in high-quality environments and only detected under environmental stress. Measurement error can also be a significant problem, since fluctuating asymmetry is typically less than 1-2% of mean trait size. Measurements of fluctuating asymmetry over several traits are needed to more accurately estimate developmental instability, since single-trait fluctuating asymmetry tends to underestimate the relationship for developmental instability. An added complication is the fact that the expression of fluctuating asymmetry differs among morphological traits, fitness components and stress factors.

Despite these complications, fluctuating asymmetry may be an important indicator of fitness and environmental stress. This relationship may be due to direct or indirect effects. As our knowledge of the mechanisms of developmental instability increases, the application of fluctuating asymmetry as a tool to understand these patterns will become more useful.

Fly strike

Fly strike (also known as fly-blown) is a cutaneous myiasis caused by parasitic dipterous fly larvae feeding on the host's necrotic or living tissue. This disease is common in sheep. The female flies lay their eggs on the animal in damp areas, mainly in the urogenital or anal areas. The eggs hatch within a few hours and the larvae begin feeding on the animal's tissue, rapidly leading to bacterial infection and possibly **death** if left untreated. Fly strike in sheep is of particularly significant economic and **welfare** importance. Prevention can include general good **health**, good hygiene, regular monitoring of the animal, **mulesing** and tail docking (see: **Docking - tail**).

(SL)

Foie gras

Foie gras (or 'fat liver' in English) is a French delicacy in which the fattened liver of a duck or goose is made into a pâté, the taste of which is described as rich and buttery. Migratory birds, such as ducks and geese, are used for foie gras as they have a high capacity for weight gain, especially in the liver, and in the wild may double their weight when preparing for migration. Birds in foie gras production are fed forages for the first few months of life, then the gavage or 'completion of fattening' phase begins in which birds are force-fed through a funnel fitted with a long tube (gavage) that forces the feed into the animal's oesophagus. This feed is usually comprised of maize boiled with fat, and is fed for 12-15 days twice a day for ducks, and 15-18 days up to four times a day for geese, with the birds receiving approximately one-third of their body weight in feed each day. The end result is a liver with fatty deposits approximately six to ten times the size of an ordinary liver. Around 75% of the world's production and consumption of foie gras is in France, with roughly 24 million ducks and half a million geese slaughtered each year, with the USA and China also having large markets.

Production of foie gras is controversial, and its production and sale have been banned in a number of European Union countries. Criticisms of force-feeding include the potential for oesophageal damage and increased risk of infection from the gavage, and impaired liver functioning from the excess fat deposited. As the liver increases in size, the abdomen becomes distended and the liver puts pressure on other organs, making breathing and walking difficult. Additionally, during the force-feeding phase birds are usually kept in small cages that do not allow for much movement or performance of many normal behaviour patterns, and the birds may undergo **beak trimming** at a young age to decrease **feather pecking** and **cannibalism**. In addition to the animal welfare concerns associated with foie gras production, recent research has found a possible link between foie gras and amyloidosis-related disorders, such as Creutzfeldt-Jakob disease or bovine spongiform encephalopathy, and Type II diabetes. However, more research is needed to establish this link more convincingly.

Follicle-stimulating hormone (FSH)

Follicle-stimulating hormone is a glycoprotein hormone produced in the anterior **pituitary gland** that stimulates the maturation of the germ cells in the **gonads** of both sexes, i.e. in the female it causes the growth of the follicles in the ovary (hence the name) and in the male it stimulates the sertoli cells of the testes, which control the maturation of the spermatozoa. The release of FSH is controlled by the release of the peptide hormone **gonadotropin-releasing hormone (GnRH)** from the **hypothalamus**. FSH production - and thus fertility - can be suppressed as a result of chronic stress, which (together with an increase in **endorphin** and **enkephalin** levels) suppresses the release of GnRH, although the effect does not appear to be reliable, and FSH levels are not widely used in this context.

(DSM)

Follower species

Among the **precocial** ungulate species, those in which the young immediately start moving around with their mother and keep in close contact with her are designated as follower species. They are generally considered to be the opposite of the **hiders**. Either strategy relies on the early establishment of a strong mother-young bond (**see: Bonding - parentoffspring**). The mobility of the young follower, combined with birth synchrony, which leads to a large number of young animals being present at the same time, is part of an anti-predator strategy based on flight and protection gained from the group in open habitat.

(SL)

Footrot

Footrot is the term given to a painful condition in which bacteria infect the hoof of **sheep** or, less commonly, cattle, **goats** and **deer**. A major problem in many temperate sheep production systems, footrot is caused by two different bacteria - *Fusobacterium necrophorum* and *Bacteroides nodosus* - but the latter invades the skin only if it has already been damaged. *F. necrophorum* can survive for considerable amounts of time in many weather conditions and situations, though infection rates increase dramatically with wet conditions.

The condition causes **lameness**, as the animal finds it painful to bear pressure on the affected foot. In the worst cases the animal is unable to walk. Other symptoms range from a distinctive nod when walking (mild) through hobbling, stopping to hold a hoof off the ground and, in some of the most severe cases, not being able to use either front leg. One distinctive sign is highly discoloured knees.

Footrot has a detrimental impact on the **welfare** and productivity of affected animals. Feed intake is reduced, especially if the flock is fed concentrate, as affected animals cannot compete equally at the feeding trough. Painful feet also hinder effective mating, especially in countries like the UK where the autumn mating season corresponds to the warm, moist weather conditions that favour severe outbreaks.

Housed animals are particularly at risk from footrot, and thus the regular provision of clean bedding is essential. Treatments include the use of antibiotics and foot trimming (cutting away the overgrown hoof). This stops the hoof from rubbing and damaging the soft flesh and, more importantly, allows air to reach the **inflammation**. Neither of the bacteria responsible can survive in the presence of oxygen (Henderson, 1990). Spraying with an antibiotic aerosol is typically used after trimming.

For control of footrot, farmers may use footbaths (containing formalin or zinc sulfate) in conjunction with foot trimming. Contamination with mud and dung decreases the effectiveness, and often the time each animal spends in the footbath is inadequate. In conjunction with these treatments, eradication is possible by selection of resistant ewes, culling of the worst cases and utilization of clean pasture, though difficult in practice.

Foraging behaviour

Foraging behaviour is the set of actions an animal takes to acquire energy and nutrients through **feeding**. The foraging behaviours used by an animal have evolved in concert with the physiology and morphology of the animal and the environment in which it exists. For example, **grazing** animals are herbivores found in vegetated areas, having specialized digestive systems that allow them to break down plant cellulose for energy. The set of behaviours used may be determined either by the individual (e.g. a grazing moose) and/or a group of individuals (e.g. a pack of wolves capturing a deer). For the moose, the foraging behaviour is one of a solitary animal moving through its environment locating specific types of vegetation on which to browse. For the pack of wolves, the foraging behaviour is one of a group of animals working together to bring down the deer so that all members of the group can feed.

The selection of food items for consumption by a foraging animal is dictated by many factors such as taste (e.g. clover versus grass for a horse), size limits (e.g. food items smaller than the gape limit of a fish's mouth), ease of capture (e.g. fastmoving minnow versus slow-moving snail), visual markings (e.g. avoidance of toxic insects by birds based on markings on the insect), abundance (e.g. more abundant food items may be easier to obtain in quantity) and energy content (e.g. a lowcaloric-density insect versus a high-caloric-density fish).

Food availability and the condition of the animal affect the degree of **selection** an animal uses in deciding whether or not to consume specific food items. If a preferred food item, based on the selection criteria used by the animal, is present in adequate amounts an animal will tend to feed primarily on that food item. If the preferred food item is not available or is scarce, an animal will tend to feed on less preferred items. For example, a fish may prefer to feed on other fish but feeds on insects because no other fish of a size within the gape limit of its mouth are available, while insects are available. These behaviours are further affected by the recent foraging history of the animal. If an animal has been feeding successfully and has good energy stores it will tend to be more selective in what it chooses to consume, even choosing not to consume readily available, less preferred food items while searching for more

P.273

preferred food items. If an animal has not recently been successful during foraging efforts and the state of its energy stores has been declining, it will tend to be much less selective in the food it chooses to consume, feeding on any food available.

Other factors that influence the degree of behavioural selection employed include the presence of intra- and interspecific competitors and predators. The more effective an individual animal is as a competitor (e.g. faster, stronger, more observant, etc.), the more selective it can be in the presence of other competitors. Less effective competitors can not be as selective in choosing what to consume and must feed on less preferred available food items in order to survive. The presence of potential predators alters which food items are selected, based on the perceived degree of threat that a predator presents when feeding on the various food items available in different habitats. For example, a small fish may prefer a particular aquatic insect found in open water but feeds on a less preferred insect that is found in shallow, inshore waters because feeding on the latter results in less exposure to predation from larger fish.

The selective aspect of an animal's foraging behaviour is further influenced by prevailing environmental conditions (e.g. for fish, oxygen levels, temperature, ammonia concentrations, presence of toxins, etc.) in which their food is found. When preferred food items are found in conditions that are marginal for survival and may even be life threatening (e.g. below critical oxygen levels necessary for survival), an animal may choose a less preferred food item in a less threatening environment and/or spend only limited time foraging in the marginal and/or life-threatening environment. For fish, this may mean that they enter waters in which oxygen levels are below the critical level necessary for long-term survival for only very short periods in order obtain a preferred food item.

The type of food item being consumed and the habitat in which it is found help to determine the foraging behaviour employed by an animal. For instance, the sea otter uses its ability to swim in order to successfully feed on fish and molluscs found in the ocean. The leopard uses its ability to stalk and rapidly pursue its prey in order to feed on antelope on the open plains.

Foraging behaviours can be either passive or active and may be different for different species feeding on the same food item. The classic passive foraging behaviour is demonstrated by the sit-and-wait predator (e.g. antlion and many species of fish) that camouflages itself, waits for its prey to come to it and then swiftly attacks to capture the prey. Active foraging behaviour encompasses a wide range of behaviours used in the search and/or pursuit and capture of food items (e.g. grazing by sheep, a hawk feeding on rabbits, lions feeding on zebras). An example of how different foraging behaviours can be employed for the same food item is one in which one species of fish captures an insect on a tree branch overhanging the water by leaping from the water to grab the insect, while another species of fish grabs the insect once the fish has knocked it into the water through the use of water as a projectile.

Finally, the foraging behaviours employed by an animal are determined by all of the factors previously described (i.e. food item, availability, prevailing environmental conditions, presence of competitors and predators, etc.). These complexities associated with the act of foraging with which an animal must contend are the reasons why there is such a wide range of foraging behaviours employed among and within species - and even within an individual animal. It is this continuously evolving repertoire of foraging behaviours available to animals that allows them to be successful in the complex environments in which they exist.

Forced mating

Within a free-range environment, animals will display **courtship behaviour** prior to copulation. In doing so, the state of receptiveness of the female is manifested, and both the male and female are physiologically prepared for impending copulation.

This contrasts with the commercial breeding of some domestic species, in which it is considered normal for the female to be restrained for mating. Examples arise in **dog** breeding, where bitches are muzzled and prevented by manual restraint from crouching and spinning, and in **pig** breeding, where boars may be given access to sows that are tethered by the neck and thus prevented from escaping copulation when non-receptive.

In domestic **horse** breeding, in-hand mating, rather than paddock mating in which the mare and stallion are at liberty to court and copulate without human interference, is common. For in-hand mating, mares are commonly restrained, sometimes chemically and often physically (with hobbles and/or a **twitch**). In-hand mating is favoured for many reasons. These include: (i) its convenience (being conducted during the working day); (ii) its commercial advantages that optimize the use of a valuable stallion and avoid him servicing only specifically favoured mares; and (iii) its perceived safety, as the mare's behaviour can be managed. This has merit but, if the female is ready for mating, **restraint** should not be required. Forced matings have been likened to rape by some observers.

There are significant differences between forced matings and those that occur in a natural situation. Neither the male nor the female is able to exhibit normal courtship behaviour, and even intromission by the male may be different, often being more forceful and curtailed to the minimum duration of contact necessary for ejaculation. Consequently, the **welfare** of animals is compromised during this process. It is not surprising, therefore, that the conception rate from forced matings is often reported to be significantly lower than for natural situations.

(AW-S)

Forced moulting

Moulting refers to the replacement of old **feathers** by new ones. Natural moulting is stimulated by the decreasing day lengths preceding winter. Poultry moult naturally about once a year to maintain good plumage and, during this moult, stop laying so that energy can be focused on feather growth. The birds will halt **egg production** for around 2 weeks, and this

P.274

allows the reproductive tract to rest and repair itself. After the moult, egg production will peak at a slightly lower level than before, but the eggs will be of a higher quality.

Forced moulting is performed after the hens have had a year of egg production and when the numbers of eggs laid have dropped, egg quality is lower, the bird's skeleton is depleted of calcium and the hen is overweight. If hens were switched to shorter day lengths at this point, they would gradually stop egg production and would moult naturally. However, this would be a slow process and hens would start and stop moulting at different times. Forced moulting shortens the non-productive period to about 8 weeks.

Forced moulting involves artificially stimulating a whole flock of hens to moult simultaneously. This is usually achieved by shortening the hours of light provision and withholding feed from the birds for 5-21

days at a time or until they have lost 25-35% of their initial body weight. Mortalities of 1.25% are expected during this feed withdrawal. After the moult, egg production and egg quality increase. Not all producers withdraw feed altogether, while others combine feed withdrawal with a period of water withdrawal. An alternative technique involves feeding the birds a low-quality food during the moult so that, although the birds will not be starved, they will still lose weight due to poor nutrition.

The most obvious **welfare** concern involved with forced moulting is the **starvation** of flocks of birds. In fact, this practice has been banned in most European countries and Canada because it is considered cruel and violates the **five freedoms**. The increased **mortality** rate that occurs can also be considered a crude indicator of the decreased welfare during starvation. **Chickens** have evolved to be highly motivated to forage and consume food continuously throughout the day. Thus, deprivation of food acts as both a psychological and a physiological **stressor**. Frustration of feeding can also lead to increased **aggression** and stereotypic object pecking, which are signs of decreased welfare.

A further concern involved with forced moulting is the increased shedding of *Salmonella enteritidis* by hens subjected to this procedure. The USDA Farm Animal Well-Being Task Group estimated that human salmonella infections from eggs could be reduced by 2.1% if forced moulting was eliminated and alternative practices adopted.

Fostering

In general terms, 'fostering' refers to bringing up and nurturing; specifically, it can be defined as the provision of parental care and nurturance to unrelated offspring. Spontaneous adoption and provision of care to others' young occur widely throughout free-living animal communities in response to a variety of circumstances. In domesticated species, artificial fostering is common in pig production, but more difficult and less frequently used in other species.

Fostering is used in commercial pig production to equalize litter sizes. Selection for larger litters has meant that domestic sows may sometimes produce 18 or more live piglets, yet they generally only have 12 or 14 viable teats, and can therefore only nurse this number of piglets. Producers also use fostering to produce 'litters' of equal body weight, and sometimes single-sex litters. Fostering in pigs is generally quite straightforward, and simply consists of removing one or more piglets from a sow and transferring them to a foster-mother. This procedure is best done as early as possible after farrowing, ideally within 24–48 h. By about 3 days, unused teats will have dried up and it will be difficult for an additional, newly resident piglet to obtain milk. For several days after giving birth sows appear unable to distinguish their own piglets from aliens and will not usually reject foster-piglets. The reason that sows do not recognize their own litters immediately is thought to be evolutionary: in a natural environment, sows will distance

themselves from group members before farrowing and give birth in secluded nests, remaining alone with their litter for a week or more. Therefore there is no need for a dam to recognize her offspring, since the only piglets present in her nest will be her own. Recognition between sow and piglets develops gradually over several days (**see also: Sow behaviour**).

Sows are likely to show **aggression** if they receive foster-piglets 4 days or more after they have farrowed. Piglets fostered after 7 days do not gain weight at a normal rate. However, older piglets can successfully be fostered on to a sow that has recently farrowed. As an alternative to weaning, older 'runts' may occasionally be fostered on to a newly weaned sow that still has lots of milk, although these sows are very likely to recognize fostered piglets as aliens, which can lead to problems with **rejection**.

If carelessly carried out, fostering may stimulate aggression (from sow to piglets and between piglets) disturbance and impair milk intake and growth, negatively affecting the **welfare** of piglets and sow. The nursing/suckling sequence is a complex series of interdependent **vocalizations** and behaviours, susceptible to interruption by noise or other types of disturbance. Disturbance at the time of nursing can inhibit the sow's milk letdown, leading to incomplete **nursings**. This is more likely to occur once piglets have established a **teat order** within the first few hours to days after birth. Once the teat order has been formed, piglets return to their 'own' teat at each suckling and, if alien piglets are introduced, there can be competition between resident and alien piglets for control of the same teat. Immediately to several days after fostering, fostered piglets may be absent from successful milk letdowns. While repeated fosterings are stressful and likely to reduce piglets' body weight at **weaning**, judicious fostering can reduce pre-weaning **mortality** and increase growth and weaning weights of piglets that would otherwise have been disadvantaged.

While the frequency of fostering will depend on unit policy, manager preferences and the reasons that fostering is used, and so may vary with time, on an average pig farm a significant proportion of piglets and sows are likely to be involved in fostering. The procedure is easier in an intensive situation, so

P.275

likely to be more common and involve higher proportions of animals on indoor, **farrowing crate** units than those using other farrowing systems. Piglet fostering is easier in larger units, where several litters of the same age will be available for exchange. On most pig farms, breeding is synchronized so that farrowing occurs ideally over 1 or 2 days each week. Some units organize farrowing in batches every 3 weeks - a labour-saving measure, which also maximizes the number of same-age litters and so facilitates easy fostering.

In cross-fostering, two or more litters are completely mixed then reallocated to foster mothers. Large piglets may be put on to one sow and small ones on to another, or the procedure may be used to form single-sex litters. In pig farming, cross-fostering is sometimes used as a synonym for fostering. Cross-fostering also refers to a research method whereby infants are transferred from their birth mother to be reared by an unrelated female (possibly even of a different species) in order to separately examine the effects on their development of genetics and environment. Shunt-fostering in pigs is a more complex procedure involving several steps and litters: the oldest litter is weaned early, while a litter about 1 week younger is moved to the first sow. A litter younger still is moved to the second sow, and the step can be repeated again, resulting in a litter-free, newly farrowed sow that is then free to act as a foster-mother for an entire litter.

Sows' universal acceptance of offspring in their nests contrasts with other domestic species such as cattle and sheep, in which dams develop recognition of their own offspring very soon after birth and will reject aliens. Near-immediate bonding is necessary in these animals because they may give birth in groups, or mothers may leave their offspring soon after birth to forage. In these species, fostering is more difficult, as the dam is likely to recognize and reject the alien offspring, and is therefore performed only in exceptional circumstances, e.g. the **death** of a cow or ewe. Giving the alien infant the appearance and/or

smell of the dam's own newborn (for example, by covering it with the skin of the dead infant or a jacket soaked in birth fluids), using a masking odour, tranquillizing the dam or restraining her while enforcing contact with the foster infant may facilitate acceptance. In cows, presenting the foster-calf immediately after the cow has given birth, while she is in the **sensitive phase** of maternal awareness, increases the chance of it being accepted as her own.

(MH)

Fowl hysteria

Fowl hysteria (or avian hysteria) is a condition in which otherwise normal **chickens** seem to react with **fear** and become highly excited and out of control, running and flying without provocation. Bouts of hysteria are cyclic in nature, with periods of activity from 1-3 min long that occur every 5-30 min. Affected birds are very susceptible to any unusual movement, noise or light and these can also initiate bouts of hysteria. Most cases of fowl hysteria have been observed in growing birds from 7 to 17 weeks of age and, once an outbreak of hysteria has occurred in a flock, it generally continues for weeks or months. The appearance of fowl hysteria is thought to be linked to the **intensification of animal production**, as it is usually found in barren, stressful and crowded conditions. In addition to poor housing conditions, fowl hysteria is also an animal **welfare** concern due to the damage the birds can do to each other during bouts of hysteria. When hysteric, birds can trample each other, fly into walls and windows, pile up and possibly suffocate each other. Study of fowl behaviour has led to the use of partitions in poultry houses, which has been successful in controlling fowl hysteria by separating eating and resting areas and allowing birds to escape from each other, reducing **social stress**.

Free-range animals

All non-human animals are influenced by humans to greater or lesser degrees, but for free-range animals this influence is reduced compared with animals that are confined to a small area, cage or container in a building, or in a pen or yard, i.e. those that are kept/housed 'intensively' (**see: Intensification of animal production**). Free-range implies that the animals are, at least, partially independent of humans and are able to move unrestricted over relatively large areas of land, in contrast to intensively kept animals that are almost entirely dependent upon humans for their care and management.

The extent of human influence and control places animals into certain categories:

- Domesticated: humans exert the greatest control over domesticated livestock, **laboratory** and **companion animals** and, particularly, those confined in small areas.
- Captive: captive animals in zoos and wildlife parks are influenced by humans in a way similar to domesticated animals, but there is less control of their **breeding**, particularly in relation to selection for specific characteristics and traits.

- Semi-wild: animals in nature reserves and parklands generally experience little direct human control, except when populations exceed the carrying capacity of the areas to which they are restricted (artificially or naturally), and then individuals may be culled.
- Wild: wild native and **feral** animals live independently of humans and there is no human control or deliberate interference, except for the **slaughter** of individuals for consumption and/or population control, or where there is conflict between human and animal interests, as for animals regarded as 'pests', which usually results in **culling** of the animals (**see: Pest control - ethics of; Wildlife management**).

Free-range animals are represented in all of these categories, but within the domesticated and captive categories there is also considerable variation in the extent to which the animals are independent of humans and free to move. For example, among domesticated livestock, the term 'free-range' is used to describe **chickens** and **pigs** that are confined to relatively small areas of land and are given the majority of their food and water by humans. In contrast, free-range **cattle** and **sheep** can roam over hundreds of square kilometres and have to find their own food and water, although food and water sources may be supplemented in some instances.

P.276

There is a general perception among people in most developed countries that the low level of human management (or interference) experienced by free-range animals actually results in superior **welfare** compared with their intensively kept counterparts. This perception appears to be based on the belief that situations allowing animals to range free and providing greater freedom for them to express their normal behaviour patterns are good for the animals, while those that confine animals and restrict their behaviours are bad (**see: Confinement**). Following this line of argument leads to the conclusion that wild animals have the highest standards of welfare and domesticated ones have the poorest. This is patently not the case when one considers the consequences of disease and **parasites**, **predation**, climatic extremes, food shortages and so forth. The welfare issues for the animals are clearly illustrated even if only free-range livestock, all of which are cared for by humans, are considered. In addition to being provided with food and water, free-range chickens and pigs are generally provided with man-made shelters, protection from predators, regularly treated for parasites and disease and promptly treated for injuries. In comparison, free-range cattle and sheep have to find their food, water and shelter, are subject to predation, treatment for parasites and disease may be limited and injuries may not be detected to allow prompt treatment.

Certainly, depending upon the level of human intervention, the ability of free-range animals to perform normal behaviour patterns can be critical for their survival. One consequence of reduced human management is that the environment of free-range animals tends to be much more variable and extreme than the environment of intensively kept animals. This means that the animals in these variable environments must be flexible if they are to survive, and their behaviour, together with their physiology, gives animals the ability to adjust and adapt to their environments (**see: Adaptive**). **Wild animals** rely more or less completely on the flexibility of their behavioural and physiological mechanisms to survive, while, at the other end of the spectrum, domesticated species are heavily reliant on humans to provide a stable environment. The extent to which the 'natural' capacities of domestic animals have been changed presumably depends upon the intensity of **selection**, during domestication, for particular characteristics.

Both natural and artificial selection have contributed to adaptation and survival, and their relative contributions will depend upon the level of intervention by humans. For wild animals, selection will be largely natural, although selective harvesting/culling will lead to artificially induced changes in the population. Artificial selection plays a much greater role in domesticated species, as humans often determine which animals survive and then select which animals will reproduce. However, in some free-

range animals, e.g. cattle and sheep, natural selection may be expected to play a greater role, because humans have less control over the survival of individuals, even if they control partners for reproduction.

Adaptation is a key factor in reducing welfare problems. In any given environment, some populations, **breeds** and individuals will be less prone to parasitism and diseases, and less susceptible to thermal **stressors**, nutrient shortages and so forth. For example, some breeds of cattle are more resistant to certain endo- and ectoparasites and show greater heat tolerance and more efficient utilization of poor-quality pasture. In harsh tropical environments, these breeds have improved welfare and productivity compared with breeds that do not have these adaptations. However, placing these tropically adapted cattle into a cold, temperate environment would severely compromise their welfare because they are not adapted to that environment.

Some of the factors that affect the behaviour and welfare of free-range animals include the following.

Environmental hazards

Environmental hazards include flooding and fires, having the potential to cause **injury** and **death**. Animals that have a good knowledge of the home range or territory may be able to escape the hazard, or seek and find refuges. Animals that are restricted in their movement by fences or natural barriers may be unable to escape the dangers.

Shortages of food and water

Shortages may be a result of natural fluctuations or could be caused by animals being confined, artificially or naturally, to an area too small to support the population. Animals that normally migrate seasonally to avoid food shortages may be prevented from doing so, and this could result in food shortages. To prevent starvation in such situations, animals in the care of humans require their natural food source to be supplemented.

Animals may also suffer through the shortage or absence of specific nutrients in their diet. Again, those animals managed by humans require supplementation, while wild animals may be able to locate natural sources of the nutrient in their home range, provided any restrictions to their movements do not prevent this.

For **grazing** free-range animals there can be an interaction between the location of water and feed in some environments. For example, in arid areas the position of the water source may restrict the area that is used for grazing because the animals will need to return to drink on a regular basis. This can result in overgrazing of the land around the watering point and, potentially, animals could starve even though other parts of the paddock or pasture might contain ample food.

The animals' abilities in relation to foraging and diet selection will also affect welfare. Foraging and selection strategies will be influenced by the time it takes to search for and consume a specific food type, the relative nutritional qualities of the food, its ease of digestion, whether it contains toxic substances and so forth. There are situations in which free-range animals have suffered and died from consuming toxic substances, for example through consumption of poisonous plants. Such situations generally arise when grazing animals are placed on pastures containing plants with which they are unfamiliar, or when they are suffering from food shortages as a result of overgrazing.

Some individuals may experience food shortages or have access only to poor-quality food as a result of their rank within the social **hierarchy**.

For free-range animals there may well be a trade-off between feeding and exposure to risks, such as climatic extremes and predation, and this trade-off is likely to be greater in situations where there is reduced human management.

P.277

Predation

Predation causes considerable suffering through injuries inflicted on the prey animal. Young animals and those that are sick or injured are most vulnerable to predation. Group members remain vigilant for predators when grazing and, should an attack take place, mothers will defend their offspring by attacking the predator. In some species, in the face of attack from predators, the adults - and males in particular - will form a protective cordon around the young.

Humans are obliged to protect from predation, as far as possible, animals in their care. However, for some free-range animals, such as grazing species that are allowed to roam large areas, it is extremely difficult to provide this protection. In such situations, the method usually adopted is to control predator numbers to reduce the probability of predator attacks, but methods of **predator control** can, in themselves, cause welfare problems.

Climatic extremes

Examples such as high heat and humidity, or cold temperatures in combination with strong winds and/or precipitation, are a threat to welfare if animals are unable to shelter, and animals may suffer from hypo- or hyperthermia. To avoid **heat stress**, animals will seek out and stand in shade or even in cool water (**see: Shade-seeking behaviour**). When resting, they may dig a scrape in a shaded place to expose a cooler surface and lie fully or semi-recumbent to maximize contact with the cooler area. To avoid **cold stress**, animals will huddle together against walls, rocky outcrops or vegetation, or in depressions in the ground, to get shelter from the wind. An inability to shelter generally results from animals being confined to areas in which there is no shelter (natural or artificial), or there is insufficient shelter, resulting in competition for it. Crowding beneath shade can exacerbate heat stress because air movement around the animals is reduced. Animals low in the social hierarchy are the ones most likely to be unable to gain access to shelter.

Diseases and parasites

Diseases and parasites will jeopardize the welfare of animals that do not have some natural resistance to them. Animals will have some resistance to endemic diseases and parasites, but may experience considerable suffering from exotic diseases and parasites until they develop resistance. This is illustrated in the use of disease to control populations of pest animals, for example myxomatosis to control rabbits. Many diseases can be prevented, or their effects attenuated, through vaccination.

Grazing animals will attempt to alleviate the effects of ectoparasites, such as biting flies, by grouping together, swishing tails and stamping hooves or walking under low vegetation. Rubbing against vegetation and rolling on the ground may help to dislodge flies and ticks. For animals in the care of humans, further protection from ectoparasites can be provided by the administration of pesticides in sprays, rubs and dips.

If animals become ill there may be limited opportunity for timely treatment because the illness may not be detected promptly. Even if detection is rapid, there can still be considerable practical problems in capturing and restraining animals for treatment. Indeed, in some instances capture and restraint may exacerbate the welfare problem and **euthanasia** may be the best solution.

Injury

Many instances of injury will threaten the welfare of free-range animals because, as with illness, in many situations there will be limited opportunity for prompt human intervention to alleviate pain and suffering. Many free-range animals in the care of humans may roam over considerable areas and, as a consequence, it is impossible to closely monitor and check every animal frequently. If an injury that requires treatment is detected then the animal has to be restrained or moved to restraint facilities, and these actions could compromise welfare further. In some situations euthanasia is the most appropriate action.

Culling

Culling involves the killing of particular individuals or capturing them for relocation. Killing animals is not a welfare issue, provided it is done quickly and humanely, with minimal **suffering** caused to the animals. The main risk with killing free-range animals is that unsuccessful attempts will result in a slow, painful death and/or injury.

In addition to the adverse impacts on welfare as a result of possible injuries, culling may cause welfare issues in any animals that are dependent upon a culled animal, such as offspring that may die from starvation. If large numbers of animals are culled in a particular area then there may be adverse impacts on the welfare of other species in that area, such as the predators and prey of culled species. Culling can also lead to the breaking down and disruption of social relationships.

Specific management practices

Culling may, in some instances, jeopardize the welfare of free-range animals more than the same practices conducted on animals that are more intensively kept, as a consequence of the size of the areas over which the free-range animals move and the relative infrequency with which the animals are closely handled. Free-range animals may be more fearful of humans because of their limited exposure to and experience of them, and this greater **fear** has the potential to compromise welfare in any situations in which the animals are in close proximity to or are handled by humans.

The extensive nature of keeping free-range livestock means that animals are gathered from large areas and this can result in heat stress, dehydration and exhaustion. Costs are high in gathering animals from large areas and so they tend to be gathered, for the conduct on them of various procedures, a small number of times per year. This can mean that invasive husbandry procedures, such as **castration**, **dehorning** and tail docking (**see: Docking - tail**) are not performed at optimum times. **Restraint** and **handling** stress are likely to be greater, wounds larger and healing times slower when animals are older and larger.

(JCP)

Frustration

The term 'frustration' is used in many different ways: (i) the motivational and/or (ii) affective state that results from being thwarted or blocked from a goal; (iii) the emotional state elicited by non-reinforcement of a response that previously

P.278

was reinforced; and (iv) the procedure of blocking or thwarting of behaviour (which may or may not lead to an emotional state of frustration). Thus, like the term '**stress**', the term frustration has many different usages that can become confused, and this confusion is confounded further by the frequent use of the term in a more general way outside of a scientific context.

Since it difficult to know the emotional state felt by an animal, even though such outcomes are of **welfare** importance, it is perhaps more useful to use the term in a scientific context to refer to those of the animal's responses to thwarting or blocking that can be objectively observed. This definition of

frustration also distinguishes the term from the emotional consequences of deprivation, which might otherwise also be referred to as frustration.

For example, laying hens in battery cages without a suitable substrate to perform **dust-bathing** behaviour are deprived, but not necessarily frustrated in this latter sense, whereas hungry cows that want to get to the feeding station but whose way is being blocked by dominant **conspecifics** are being frustrated. However, this distinction between deprivation and frustration may be false since, if the performance of a specific behaviour is rewarding in itself (**see: Behavioural need**), it might be argued that deprivation of this activity results in the same process of non-reward as might occur when an animal is blocked from some external stimulus. Thus, whether a behaviour is self-rewarding or enables an animal to achieve a certain goal (e.g. food, a nest, access to a mate), then preventing the occurrence of the behaviour is a form of frustration that may lead to a state of emotional frustration, suffering and reduced welfare.

Behavioural expressions of frustration include: **ambivalent behaviours**, **displacement behaviours** and **redirected behaviours**, which may appear unrelated to the original context of the frustration. For example, many animals that are physically prevented from reaching food when they expect to feed show pacing, **aggression** or **grooming**, behaviours all indicative of frustration in this situation. Some animals also seem to express their frustration vocally (e.g. the gackel-call in laying hens). Abnormal injurious behaviours (e.g. **feather pecking** in laying hens, **tail biting** in pigs) and stereotypic behaviours (e.g. sham chewing in pigs, **tongue-rolling** in giraffes) are often observed when animals are confined and restricted in the performance of certain behaviour patterns. Stereotypic behaviours may result from the blocking of **foraging behaviour**. In addition, the specific form seems to be predicted from the type of natural foraging activity (e.g. Clubb and Mason, 2003).

Behavioural signs of frustration, however, do not tell us exactly how motivated or frustrated an animal is. The strength of the **motivation** to perform the behaviour determines the intensity of frustration and, indirectly, the effect on the welfare of the animal. This may be deduced from a range of physiological and/or behavioural measures. Behavioural demand tests can give an indication of the intensity of the motivation or frustration (**see: Economics of behaviour**). Typically in these tests, an animal has to pay a 'price' for access to a condition where it can interact with an object/conspecific or where it can perform a certain behaviour. 'Price' in this case is defined as the amount of effort an animal is prepared to put in to gain access to a preferred commodity or condition, usually by performing an **operant response**, such as pressing a lever, pecking a key or pushing through a weighted door. When an animal has to work harder to gain access to its most preferred environment but still persists, it suggests which environments or commodities are important to them.

The emotional expression of frustration may vary between individuals or circumstances. It may present as an intensification of the frustrated behaviour (anger), aggression (rage) or **depression**, and while the ability to measure such states directly is not possible, an awareness of their potential occurrence may be important.

Fur farming

Animals whose pelts are in demand are often farmed intensively; examples include **mink**, Arctic **fox**, blue fox, **rabbits** (angora) and sometimes **ferrets**. Because of the small cages involved there is normally quite a high level of stereotypic behaviour (see: **Stereotypies**) around the time of feeding, e.g. pacing, shown by the animals, which has given rise to concern and debate over the **welfare** of these animals.

GABA

Gamma amino butyric acid (GABA) is the main inhibitory transmitter in the **central nervous system** of mammals. Drugs such as the **benzodiazepines**, which act through stimulation of GABA receptors, are thought to have an anxiolytic (anti-anxiety effect) by modulating ascending noradrenergic and serotonergic input to the hippocampus, which forms part of the behavioural inhibition system (**see: Emotion**) and is involved in assessing any discrepancy between perceived and predicted events. Discrepancies, as might occur in a novel environment, result in behavioural inhibition and a heightened state of arousal, together with **anxiety**.

GABA can also have excitatory effects, especially in young animals and in insects where it has a largely excitatory effect on muscles. These opposing effects are possible because GABA receptors regulate ion flow across the membrane and so the orientation of the flow determines the effect. During development, as **neuron(e)s** mature, the polarity of the receptors may reverse, e.g. in the hippocampus and neocortex, so that GABA changes from having a stimulating to an inhibitory effect. Defects in this reversal may contribute to the onset of some forms of epilepsy. Since GABA also stimulates neuro-genesis in the young, it may also play a role in the differential effect of novelty during development, having an enriching effect and increasing brain complexity in the young, but having an anxiogenic effect in the mature individual.

(DSM)

Gait

Gait is a coordinated and rhythmic pattern of **locomotion** resulting in progressive movement (Barrey, 1999). Quadrupedal locomotion has three distinct gait patterns - the walk, the trot and the gallop - and these can be further classified as symmetrical and asymmetrical (Howell, 1944). In symmetrical gaits the gait pattern of a limb pair is repeated by the subsequent limb pair, half a stride later (Alexander, 2003). The walk is a symmetrical gait, with two, three or four legs supporting the animal during the stride and typically the order of limb sequence is left front, right hind, right front, left hind. The trot is also a symmetrical gait in which diagonally opposite legs move in phase with each other (Alexander, 2003).

During walking and trotting, there is an equal interval of time between footfalls. Asymmetrical gaits, like the gallop, have no symmetry to the motion cycle - the time between footfalls is not equal (Alexander, 1992), and the gait pattern of a limb pair in the first part of the stride is not repeated by the following limb pair (Dagg, 1977). During the gallop, the two feet of a limb pair strike the ground in rapid succession, followed by a longer period before the next limb pair is set down (Alexander, 1992).

Terrestrial locomotion in birds is limited to four gait patterns - the walk, the run and the hop, with legs in -phase or out-of-phase. During walking and running the left and right legs alternate, half a stride out of phase with each other (Alexander, 2003). Birds may not use every gait pattern; for example, chickens use the walk and the run but rarely the hop.

Until recently, gait in farm animals had not been investigated thoroughly, but this is changing due to increased concern about animal welfare and the economic costs associated with lameness. Currently, two approaches are used to analyse gait: subjective assessments and objective biomechanical measures, such as those from force platforms, kinematics, electromyography and accelerometers.

Game animal

Game animals are defined simply as any free-ranging animals hunted for subsistence, spiritual or recreational purposes, but lurking beneath this simple definition are complex issues involving population **ecology**, animal behaviour, genetics and **evolution**, **conservation** policy, land management, human rights and **ethics**. It is perhaps unfortunate that the English language also employs the word 'game' in reference to human endeavours specifically oriented towards competition, caprice and manipulation (although the definition of 'game' used above is independent of the word's other meanings, and indeed may pre-date them). As the discipline of wildlife management has broadened to adopt an ecosystem-centred view in Western cultures, 'wildlife' has increasingly been adopted by management agencies in preference to 'game'. Central to the concept in any case is that wild animals are deliberately killed to meet human needs or desires.

Hunting as a human endeavour pre-dates historical documentation; meat is an accepted part of human diets in most cultures and leather remains a popular and useful material. Since the era of domesticated animals, however, most humans have faced choices: consume animals cultivated specifically for human use or consume animals that have evolved principally from the forces of natural selection. Although most meat and

P.280

leather used by humans is now undoubtedly of domestic origin, hunting has not disappeared from many cultures, nor is there any indication of it doing so soon.

Population biologists have a fundamental understanding of the patterns expressed by species commonly hunted, but have rarely developed specific models of carrying capacity- and population-level responses to hunting on geographic and temporal scales of interest to human societies. This may seem surprising, given

the ubiquity of hunting, but is understandable when considering the complexity of forces affecting any given animal population. Because hunting as a human activity long pre-dated modern science, most management and control of hunting developed from taboos, traditions or rules of thumb rather than from experimentally derived data. Still, it is difficult to deny the success many modern societies have had in maintaining game populations in the face of increasing human density and modern weaponry. In short, most vertebrate populations equilibrate in the presence of moderate, human-caused off-take because the environmental conditions faced by survivors are improved by the reduction in the density of **conspecifics**. Where management systems are mature, achieving sustainability of terrestrial species subject to hunting is now commonplace.

Deer (*Odocoileus* spp.), despite being brought close to extinction by settlers' over hunting in the 18th and 19th centuries, are probably more abundant in North America today than prior to European arrival. Wapiti (*Cervus elaphus*), pronghorn (*Antilocapra americana*) and American black bears (*Ursus americanus*) have also made dramatic (if incomplete) recoveries in the presence of hunting. Despite extensive legal hunting, native doves, grouse, quail and introduced pheasants (i.e. *Phasianus colchicus*) have avoided the unfortunate fate of the passenger pigeon (*Ectopistes migratorius*) in North America (which was hunted to extinction - both for commercial purposes and to reduce tree damage - before effective conservation measures were adopted). Underlying these recoveries has been the transformation of hunting from an uncontrolled, openaccess activity to an egalitarian, state-sanctioned one in which hunters willingly accept various restrictions in order to provide similar hunting opportunities to their neighbours and descendants. More importantly, interest in game animals has provided strong motivation for habitat protection; hunters have encouraged governments to restrict agriculture, forestry and industrial developments in deference to maintaining some wild habitats. Early hunter-conservationists in North America supported not only hunting, but also complete protection for national parks. In more densely populated Europe, hunted populations of red deer (*Capreolus elaphus*), roe deer (*Capreolus capreolus*) and various Galliform birds have also persisted (albeit under more restricted access to hunting privileges). When societies decide to prioritize conservation, hunting per se is clearly not an impediment to population persistence.

Nevertheless, even when demographically sustainable, human **predation** exerts quantitatively and qualitatively different effects on game animals than do non-human mortality sources (e.g. **parasites**, **diseases**, predators). Hunting usually changes behavioural patterns of game animals (e.g. choices of food and cover), at least during time periods when they are pursued, often to the detriment of the survivors. By altering existing social patterns, hunting can also produce cascading ecological effects, such as changing the magnitude of inter-deme gene flow, or the intensity of intra-species infanticide.

Perhaps more pernicious is that by selectively removing certain age classes (usually adult males), intensive hunting has the potential to alter the genotypes of populations produced by natural selection, resulting in species that evolve (at least partly) in response to artificial selection. In Europe, such management has often taken the form of culling animals with 'undesirable' antler forms, risking unknown pleiotropic effects (wherein a gene influences numerous phenotypic characteristics). In contrast, hunts that too intensively remove males with the largest (i.e. most desired by hunters) secondary sexual characteristics may inadvertently produce selection for males that grow slowly (as well as other, unknown genetic effects). Such artificial selection can be minimized by keeping human kill rates sufficiently moderate and/or by management regimes that produce age-/sex-specific mortality patterns similar to those with which the target species evolved.

Subsistence hunting is rarely questioned on moral grounds, as by definition the alternative is human **starvation**. Still, as human populations increase and formerly subsistence societies become increasingly integrated with market forces, subsistence hunting has often been found to be unsustainable. Solutions to overhunting for **bushmeat** usually require development of more functional social feedback systems that

prioritize long-term benefits flowing to a satisfactorily defined social group over short-term, individual benefits.

Hunters in modern Western culture have developed numerous codes of ethics, but these all presuppose that hunting itself is ethical. The morality of deliberately killing animals in the modern world is a legitimate question. Defences of hunting that call upon notions of hunters' self-restraint or their spirited defence of wildlife habitats fail to answer this ethical question directly. Ultimately, the acceptance of hunting is an individual decision, and will depend on what sort of hunting is envisaged and how one conceives of oneself in relation to the natural world. Among those to whom hunting is optional, most agree with their opponents that hunting is essentially atavistic, primitive and uncivilized. They disagree with antihunters about whether these are negative or positive values. In accepting their role as predators, thoughtful modern hunters embrace the responsibility towards wildlife that killing requires. In this moral stance, consumption of wild meat becomes not merely communion with nature but akin to Communion, a physical acknowledgement of mankind's destructive behaviours towards the natural world, and thereby a recommitment towards minimizing them.

Game theory

Why animals behave the way they do is one of the central questions in animal behaviour research. While some behaviours are easy to understand, others are much harder to predict. Game theory is one tool that can be used to help determine what, when and why behavioural strategies are employed by individuals. For example, will a male elephant seal opt to fight or flee when challenged over access to mates? Should an individual stickleback fish inspect to see whether a predator is present or let others in a group inspect

instead? Game theory is instrumental in helping to answer these questions and many other animal behaviours.

John von Neumann first developed the mathematical basis for game theory in 1928, but it was not until von Neumann and Oskar Morgenstern's book *Theory of Games and Economic Behaviour* in 1944 that game theory became recognized as a mathematical means to analyse different strategies. Games can be used to assess which strategy results in the highest pay-off, given a set of strategies and choices made by other players in the game. There are three main elements for a game: (i) two or more players; (ii) a set of strategies; and (iii) a corresponding set of pay-offs for each of the strategies. One of the goals of game theory is to determine the strategy set where each player has chosen the best response and cannot acquire additional benefits by changing their strategy given the other players' strategies. This strategy set solution is called the Nash equilibrium after John Nash, who developed the concept.

While initially used in the field of economics, game theory has since been applied to biology to model the behaviour of individuals given the strategies and behaviour of others in the population. John Maynard Smith significantly contributed to game theory in biology by introducing the concept of an evolutionary stable strategy (ESS). Equivalent to the Nash equilibrium, an ESS is a strategy that, through the process of natural selection, can become established and cannot be eliminated by any other strategy introduced into the population. In this case, the pay-offs correspond to the effects each strategy has on an individual's relative **fitness**. For a new strategy to become established and evolutionarily stable, it must yield a higher fitness than other strategies in the population so that its frequency will increase and resist invasion by other strategies with lower fitness pay-offs. Evolutionary games can be used to model the emergence and stability of behaviours in a population based not only on the benefits and costs of each strategy, but on the interactions between individuals.

One of the first evolutionary games applied to animal behaviour was Maynard Smith and Price's hawk-dove game. While simple, this game provides insight into animal conflicts over resources. Two different behavioural strategies are considered: hawk and dove. Individuals using the hawk strategy always fight for the resource and do not withdraw until either they win the resource or they are injured and lose the contest. Doves, on the other hand, will only display as a threat to fight, but will back down and relinquish the resource if the other player escalates the fight. Considering only pair-wise contests between individuals, a hawk may encounter another hawk or a dove, and likewise a dove may encounter another dove or a hawk. Each of these contests has fitness consequences, or pay-offs, as a result of either winning or losing the contest. In hawk-hawk interactions, half the time the individual will win the contest and half the time it will be injured and lose. If the contest is between hawk and dove, the individual with the hawk strategy will win the resource and the dove will lose, but not be injured. Contests between two doves result in each splitting the resource. Based on these pair-wise interactions, a pay-off matrix can be constructed using the value of the resource (V) and the cost associated with fighting (C) (see Fig. G.1).

These assumptions provide the rules of interactions and reward structure for the game. Using this pay-off matrix, we can analyse the model and determine the ESS. In this case, the ESS depends on the value of the resource compared with the cost of fighting. If $V > C$, then the hawk strategy is the only ESS because the pay-offs for hawk-hawk ($(V-C)/2$) would be greater than for dove-hawk (0), and the pay-offs for dove-dove ($V/2$) would be less than hawk-dove (V). However, neither the hawk nor dove strategy becomes an ESS if $C > V$. Instead, a mixture of hawk and dove strategies is maintained in the population at equilibrial frequencies. This mixed ESS can occur from individuals either adopting mixed strategies, where they play the hawk strategy for a proportion of the time and the dove strategy the other proportion of the time, or from individuals that use pure strategies (either always dove or always hawk) occurring at equilibrial proportions in the population. This game can be made even more complex to reflect more closely behaviour observed in animal populations by changing the assumptions of the model, adjusting the pay-off matrix or **resource-holding potential** of individuals, allowing repeated conditional interactions or adding

additional strategies, such as bourgeois or anti-bourgeois, to account for different behaviour by **territory** owners and intruders.

Another classic game is the prisoner's dilemma, which has been used to model the evolution of **cooperation**. In this game, the optimum is achieved when both prisoners cooperate with each other and remain silent when interrogated by the police. However, this optimum is not a stable equilibrium point if the pay-off to betray and testify against the other prisoner is greater than the pay-off to remain silent. The only ESS is the betray strategy, even though the pay-off is lower when both prisoners betray than if both were to cooperate - hence the dilemma. If repeated interactions and learning are incorporated into the model, a tit for tat strategy, where one player

P.282

matches the strategy used by the other in previous interactions, emerges as a potential solution if the probability of interactions with the same player is high. Thus, game theory shows how reciprocal **altruism**, as well as other behaviours, may become established in a population.

	Hawk	Dove
Hawk	$\frac{(V-C)}{2}$	V
Dove	0	$\frac{V}{2}$

Fig. G.1. Pay-off matrix constructed using the value of the resource (V) and the cost associated with fighting (C).

While games are merely simplified mathematical models of real behavioural systems, they can be used to help generate new hypotheses and test predictions generated from the model. Game theory helps to define the conditions needed for a strategy to be conserved in a population. This in turn helps animal behaviourists better understand and investigate the behavioural strategies of individuals based on their interactions with others.

General adaptation syndrome

The general adaptation syndrome (GAS) is a term coined by **Hans Selye** to describe what was believed to be the body's common response to **stress**. There are three stages to the GAS: an initial alarm phase, followed by a period of resistance leading ultimately to adaptation or exhaustion. The alarm phase, which lasts a matter of seconds, is characterized by activation of both the sympathetico-adrenal medullary system (**see also: Sympathetic nervous system**), which results in the release of **epinephrine and norepinephrine**, and the **hypothalamic-pituitary-adrenal (HPA) axis**, which results in the release of **corticosteroids**. These serve to mobilize energy reserves and prepare the animal for action, with an increase in heart rate and blood pressure and a diversion of blood away from the gut and towards skeletal muscle. Also at this time the levels of certain anabolic hormones like **insulin** fall as resources are diverted to maximize a fight or flight response. During the resistance phase the level of adrenal hormones remains high but the level of anabolic hormones returns to normal. The success of this phase depends on the magnitude of the alarm response and previous experience, which may indicate success or failure. In the event of a prolonged period of resistance due to a failure to adapt, the animal may suffer from a range of stress-related illnesses and ultimately die. The initial focus of exhaustion is related to the consequences of prolonged immunosuppression as a result of persistently high levels of corticosteroids.

The GAS in broad terms is a non-specific response that occurs in response to many psychological and physiological stressors, even those that are believed to be pleasurable, such as sexual arousal, and so it is not a sufficient indicator of compromised welfare alone. Nor is it a necessary condition for reduced welfare, because there is a range of **stressors**, e.g. hyperthermia (**see: Critical temperature**) and dehydration, that do not provoke an increase in corticosteroids (because such a response would actually exacerbate the impact of this type of stressor).

While initially useful in helping to describe how the body copes physiologically with stressors, the concept of the GAS is criticized for being oversimplistic, with more recent models emphasizing the context-specific nature of stress responses (**see: Emotion**) and need for a wider variety of measures to evaluate their impact on **welfare** (**see also: Measuring welfare**).

Generalization

The term generalization is used in relation to two different learning phenomena. Most often it refers to the extension of a response to stimuli that are similar but not identical to those with which it was

originally associated (stimulus generalization). As such the concept of generalization is the opposite of **discrimination**. Thus a dog that is taught to sit on command by a specific trainer may respond appropriately to the command 'sit' spoken by another individual as a result of stimulus generalization. While many species generalize the stimuli to which they learn a response, the response is not necessarily identical and there may be a decrement in response initially, when any of a wide range of features is changed, for example when the animal is asked to sit outdoors when it has been trained indoors. From a practical perspective, it is important to recognize and accommodate this decline so as to encourage the animal to generalize as desired.

Response generalization refers to a change in the form of the response that occurs to a particular stimulus, i.e. a wider range of behaviour occurs to a given trigger. In high-performance work this may not be desirable (e.g. obedience competition work), and differential reinforcement of only a narrow range of high level responses (**see: Operant response**) can help to minimize the tendency for response generalization.

(DSM)

Genetic bottleneck

When the number of breeding organisms is restricted, the genetic variation within the population is reduced because some genes, found in only a small number of individuals, will disappear by mere chance. Subsequent generations are genetically very different and less genetically diverse than the ancestral population as a result. Typically, rare alleles will be lost but in some cases by chance they will become greatly increased in frequency. Restrictions of this kind are termed genetic bottlenecks. Studies of fossil DNA show, for example, that **domestications** of wild species were genetic bottlenecks as the variation in the wild progenitor (such as the aurochs) was greater than that in the domesticated form (cattle). During **breed** formation, when small numbers of particularly esteemed animals were used to found breeds, further genetic bottlenecks resulted. Thus the Thoroughbred horse owes much of its ancestry to three stallions (Cunningham *et al.*, 2001) while the famous C57BL/6 and C57BL/10 strains of laboratory mice are all descended from female mouse no. 57 on the Massachusetts farm of pioneer mouse breeder and schoolteacher Abbie Lathrop (Silver, 1995).

When small numbers of males inseminate many females, this is effectively a genetic bottleneck and a rare allele can

P.283

become frequent as a result. The gene for bovine leucocyte adhesion deficiency (BLAD) became widespread in the North American Holstein breed because of the heavy use of a single bull that carried the recessive gene (Hall, 2004).

Genetic bottlenecks do not appear to have as large an effect on quantitative genetic variation (broadly speaking, inherited characteristics whose values follow a normal distribution in a population, such as body weight) as might be expected. Thus, one would not expect bottlenecks to have a sizeable effect on behaviour phenotypes, though this has not been explicitly studied.

Genetic engineering

Genetic engineering is the process of actively and directly manipulating the genetic material of an organism, with the objective of giving this organism new characteristics for which there is an agricultural, biomedical or other application. This engineering can be either *somatic* (in which the germline cells are not affected, so that the change only affects the phenotype of the engineered individual) or *germline* (in which all cells including eggs or sperm cells are affected and the change is passed on to offspring).

(AO)

Genetics of behaviour

Animal species usually have characteristic patterns of behaviour, and certain species are especially suited to domestication because of these patterns. Like all phenotypic characteristics, behaviours are expressions of interactions between the environment and the animals' genotypes. Genes code for enzymes, and behaviour is controlled by the operation of the neuroendocrine system and, to varying extents depending on the complexity of the animal, by the **brain**. Mutations in relevant genes may lead to altered forms of enzymes in these systems, leading to changes in the ways in which the systems operate.

That differences in behaviour, whether between species or within species, have a genetic basis can be tested by raising experimental animals in identical environments. This is frequently done in species such as the fruit fly and laboratory mice. Genetics of behaviour differences are sometimes very simple, even being controlled by a single gene. In some cases, a behavioural change has been observed in wild animals and the underlying genetic cause has been deduced. For example, the blackcap, a small migratory bird, has evolved a new pattern of winter migration from its breeding grounds in Germany and this clearly has a genetic basis (Berthold, 1991), while experimental populations of mink have been selectively bred to exhibit different responses ('fearful' or 'confident') to a novel stimulus (Malmkvist and Hansen, 2001).

Under domestication, certain behaviours became fixed, such as neoteny in dogs. The hypothesis would be that there had been genetic variation for this trait in the earliest domesticated dogs, which was rapidly reduced by human selection so all subsequent dogs have been uniform in this respect. But some behaviours of our domesticated animals have not changed (Hall, 2004). Our pigs are descended from wild boar, and both the domesticate and her wild **conspecific** build a nest before giving birth, though under intensive husbandry conditions this may be impossible for the farmed sow. It seems likely that the welfare consequences of preventing an animal from performing a behaviour that has a strong genetic component may be more serious than preventing the performance of one that is more dependent on environmental factors (**see: Behavioural need**).

There are several examples of the demands of modern animal husbandry having led to heritable changes in behaviour. Wild boar and wild junglefowl use, respectively, feeding strategies that are more

energetically costly than those of their domesticated counterparts. When breeds differ in behaviour, this can be an indicator of a possible genetic basis, though proper experimental design is essential.

Modern molecular genetics is leading to an understanding of how changes in genes can be linked with the appearance of new behaviours. Compared with the fruit fly, the honeybee has more complex genetic systems for **vision**, **olfaction**, **learning** and **memory** - consistent with its evolution of a social lifestyle (Honeybee Genome Sequencing Consortium, 2006).

Study of the genetics of behaviour has several important practical consequences. If **zoo animals** are to be reintroduced to the wild, care must be taken not to operate a mating system that favours traits adapting the animals to captivity - in other words, domestication of zoo animals must be avoided. With **companion animals**, while behavioural differences between breeds can be very evident (most notably with dogs), differences between individuals within breeds can also be important. For example, in Japan it costs about US\$23,000 to train a guide dog and, among Labrador retrievers, only about 30% of those trained prove suitable for use. It is claimed (Fuyuno, 2007) that variation in a gene that codes for an enzyme that, in humans, is involved in mood regulation can indicate the ability of dogs to concentrate. If so, this could lead to a valuable aptitude test. With farm animals, understanding of the genetics of behaviour could lead to development of breeds of livestock that are adapted to particular husbandry conditions. Though superficially attractive, this might be seen as ethically suspect in that, arguably, conditions should be improved to suit the animals rather than the animals being changed to suit the conditions (Hall, 2004; **see also: Ethics**).

Genome

A genome comprises all of the genetic information or hereditary material in one set of chromosomes in an organism. Humans and higher animals have two genomes - a nuclear chromosomal genome and a mitochondrial genome. Whereas the nuclear material arises from contributions from both parents as a result of fertilization of the egg to produce a zygote, the mitochondrial genome is derived from the egg

alone and so the maternal line. If the rate of mutation within DNA is known, differences in mitochondrial DNA can be used to provide an evolutionary clock for comparing species or breeds.

(LMD)

See also: **Genetics of behaviour**; **Genotype**

Genotype

A genotype is the genetic make-up of an individual, encoded in the DNA, which is the 'blueprint' for building and maintaining that individual. The genotype underpins **phenotype**; however, the expression of traits can be changed through environmental factors or the influence of other genes. A genotype includes not only the dominant or expressed genes but also the recessive or masked genes.

(LMD)

See also: **Genetics of behaviour**

Gentling

Although sometimes used in other species to describe **habituation** programmes, gentling is commonly used in **horse** handling. It is now becoming accepted as a better term than 'breaking-in' for the earliest steps in the foundation training of horses. Gentling emphasizes that fear and therefore flight responses (both in the short and long term) are controlled most effectively by **instrumental conditioning** and habituation rather than by force. Traditional breaking techniques that use roping and other forms of restraint to train a horse that attempts to escape are not to be recommended. Concern for the welfare of horses trained in this way relates to the likelihood of their developing **learned helplessness**. Similarly, this approach to training may have the disadvantage of compromising the horse-human bond and, as such, is losing favour with riders who regard their horses as **companion animals**.

Gentling techniques that expedite the formation of a bond between horse and handler are becoming increasingly popular. Operant conditioning largely based on negative reinforcement - but also some positive reinforcement - forms the basis of all such methods. Primary reinforcers can take the form of physical contact (e.g. rubbing the neck can be analogous to **allogrooming** by a **conspecific**). Mild punishment may also have a role, so the horse may learn that moving away from the handler spontaneously is associated with **aversive** outcomes such as being chased (the application of so-called pressure), an outcome that continues until the horse turns to approach the handler (negative reinforcement). As with all negative reinforcement regimes, it is critical that handlers use only sufficient pressure to achieve the desired effect and remove the pressure as soon as the correct response is made.

Opposition to gentling comes particularly from those who argue that it is time-consuming compared with traditional breaking. However, successful horse whisperers have been instrumental in countering this assertion since they can often reach training milestones faster than those using traditional restraint and force.

(PDM)

Geophagia

The deliberate eating of earth or soil. A wide range of species has been observed to exhibit geophagia, examples including species from the following classes: mammals, birds and reptiles, and indeed including humans and many invertebrate species. The advantage of geophagic behaviour was presumed to improve the intake of minerals that may otherwise be deficient, in particular phosphorus, calcium, copper and iron. However, it has recently been proposed that other advantages may be derived, involving **self-**

medication. One is detoxification. Herbivorous animals exhibit geophagia more often than omnivores or carnivores, and it is thought that such animals are at a greater risk of poisoning from plant-derived alkaloid compounds. It may be that sodium is of particular importance in metabolizing these toxins into harmless products, and sodium-rich soils have been found to be particularly sought after by animals. Aside from the mineral provision, clay (which may actually have a low mineral content) binds toxins and removes them from the body in expelled faeces. Mycotoxins and bacteria, as well as plant-derived toxins, can all be bound by clay in this way. Clay also has an antacid effect and is thought to line the intestinal wall, thus protecting it from mechanical damage by plant toxins and from bacterial and parasitic infestation. Rats have been shown to eat more kaolin (china clay) than controls when experimentally infected with pathogenic bacteria. Indeed, kaolin is used as a human medicine for gastrointestinal problems. Despite this, geophagia may also be an **abnormal** behaviour - rats have been shown to eat clay when stressed. Geophagia carries a risk of infection from soil-dwelling bacteria, nematodes and other pathogens and **parasites**.

Gestalt perception

Gestalt (meaning 'shape' in German) psychology developed in Berlin at the beginning of the 20th century. Max Wertheimer is credited as the founder of the movement, although its origins go back to the work of various philosophers, including **Immanuel Kant**. The main theoretical principle of the Gestalt psychology is the view that biological phenomena have to be studied in their wholeness. In other words, Gestalt psychologists used a (w)holistic approach to study human behaviour. This approach contrasts with the traditional physical reductionist scientific methodology, which divided the object of investigation into parts that could be analysed separately in order to reduce the complexity of the object. The Gestalt movement was particularly active and influential in the area of visual perception. According to this view, we perceive and recognize objects and figures as whole forms and not just

P.285

as a sum or collection of simple shapes, lines and curves. An example of a Gestalt perception would be the figure of a Dalmatian dog in the shade of the trees (see Fig. G.2): according to Gestalt psychologists we would perceive the dog as a whole all at once, instead of first recognizing its parts (e.g. its nose and tail) and then inferring the dog from them.

Fig. G.2. Gestalt perception predicts that the dog in this picture would be perceived without the observer first focusing on its parts.

Gestalt psychologists described a number of principles and laws that control our perception. The two most important principles are the principle of totality and the principle of psycho-physical isomorphism. The principle of totality states that perception - or any conscious process - needs to be analysed by simultaneously considering the physical and mental processes involved. The principle of psycho-physical isomorphism links conscious experience to cerebral activity.

Gestation

Gestation, also known as pregnancy, is the period of time in which a mammalian female supports the life of a **fetus** or fetuses from fertilization to **parturition**. Gestation begins when an ovum is fertilized by a sperm in the oviduct to form an embryo. The embryo then migrates from the oviduct to the uterus, where

implantation (or attachment) and recognition of pregnancy are initiated. Typically, after the embryo reaches the uterus, the mother produces an excess of **progesterone** (from the *corpus luteum*) to maintain the pregnancy, and progesterone concentrations remain high through the duration of the pregnancy. Once the embryo has migrated from the oviduct into the uterus, morphogenesis of the placenta occurs. The placenta functions not only to separate the maternal and fetal organisms, but it also serves as the fetal gastrointestinal tract, lung, kidney, liver and endocrine glands. Another important function of the placenta is to keep maternal and fetal blood separate while still allowing nutrient transfer.

As gestation continues, the uterus expands with the growing fetus. The uterus expands in three stages, although the myometrium layer remains tight to prevent premature expulsion. At the end of gestation, there is a chain of events that leads up to parturition. **Oestrogen** concentrations begin to increase, causing the pelvic ligaments to gradually become more relaxed as gestation continues, and the hormone relaxin also aids in this process. At the end of gestation, parturition is stimulated by a complex interaction of endocrine, neural and mechanical factors. The length of gestation is determined by a multitude of factors including genetic (breed and fetal **genotype**), maternal (age), fetal (litter size, sex and endocrine function) and environmental (nutrition and temperature) factors.

(ELS)

Giant panda

The giant panda (*Ailuropoda melanoleuca*) is a **bear-like carnivore** inhabiting bamboo forests of mountainous regions in China. Molecular studies confirm pandas as one of eight extant bears, but evolving separately from them since about 20 million years ago. Fossilized dental remains indicate a commitment to bamboo as its principal food source by at least 3 million YBP. Adult males may reach 1.8 m in length and over 100 kg in weight. Females are usually smaller, but size dimorphism is not rigidly evident. Pandas readily ascend trees. They usually feed in a sitting posture and can easily stand bipedally. An unusual characteristic is an enlarged wrist bone that functions somewhat like a human thumb and provides dexterity in handling food items.

As much as 90-98% of the diet consists of the leaves, shoots and stems of bamboo. Despite adaptations in the forepaws, teeth and jaws for bamboo consumption, the panda retains the digestive system of its carnivore ancestry, and is therefore unable to digest cellulose, a main constituent of bamboo. Pandas solve this problem by rapidly passing prodigious quantities of bamboo through the digestive tract on a daily basis. Mating and birth are strictly seasonal, separated by a period of about 5-7 months. A female has a single **oestrus** during the spring, lasting from 1 to 3 days. Like all bears, giant pandas undergo a delay in embryonic implantation of about 2-3 months. The period of fetal growth lasts about 50-60 days, and results in birth weights of about 110-115 g or 1/800th of the dam's weight. Twinning occurs in nearly 50% of all litters, but typically only one cub is raised. Captive pandas may live beyond 30 years in captivity, but their lifespan in the wild is estimated at about 20 years.

Consistent with giant pandas' largely solitary nature is a strong reliance on **olfaction** for **communication**. A large scent gland surrounding the anus is used to deposit olfactory messages at strategic locations within a panda community. Tree trunks, rocks or clumps of grass are used on which a mark is left that can be monitored by others. Scent is known to convey information on identity, sex and possibly social status for marking males. Males use scent to identify the areas where they live, whereas females' primary use is in signalling oestrus. Males locate oestrous females by tracking their scent. At close range auditory and visual modalities are used in courting. From one to five males attend a female in heat, engaging in often severe competition for mating.

Pregnant dams seek parturition sites in hollow bases of large trees or in limestone caves. A fetal life of only 50-60 days

P.286

results in a neonate that is highly **altricial**, depending on the dam for warmth, nourishment, positioning at the breast and stimulation of voiding. Denning is mandated for the first 100-120 days of life, soon after which cubs ascend trees for resting. Dams cuddle and position infants on their ventrum nearly continuously for the first 2-3 weeks of life. The maternal investment is such that they are typically able to care for only one infant in the case of twins, leaving the other to die. Eyes begin to open at roughly 45 days, and locomotion is seen at 75-80 days. By 14 months the dentition is sufficiently developed for bamboo consumption; weaning occurs at 18-24 months.

Giant panda populations, both wild and captive, are subject to an array of **stressors**. Few studies have been conducted on wild-living pandas, yet known circumstances imply a considerable human impact on their well-being. It is known, for instance that the species cannot survive outside the bamboo forests, but satellite recordings of a sharp decline in habitat availability in recent decades suggest that competition for resources is an ongoing process. The reproductive cycle of bamboo flowering, followed by die-off and 5-10 years for regeneration, has resulted in starvation for some populations in recent times. Bamboo cycles vary according to species and, in locales where only one or two survive, the primary food source for pandas is periodically in short supply. Because much of their natural range is shared with farmers, pandas are subject to diseases carried by domestic livestock. In some areas pandas and humans compete directly for bamboo shoots and possibly other resources. Atmospheric and water pollution have the potential to adversely affect panda well-being, as do trace minerals for populations in proximity to roads and mining operations.

Giant pandas readily develop **stereotypies** when confined in static, albeit naturalistic, captive environments. These typically include pacing, pirouetting, head tossing, exaggerated pushing off from structures, tongue flicking and body swaying. Providing enrichment is essential in ameliorating the constraints imposed by captivity. Scientific investigations have revealed that pandas respond to a range of objects, with benefit derived from their varied properties in stimulating a diversity of behavioural responses. Based on both behavioural and corticoid measures, providing individuals free choice in access to different parts of the habitat reduces their **stress** load.

Fossils from northern Myanmar and Vietnam, and across China from western mountains to eastern shores, indicate a widespread distribution of giant pandas in Asia during the early Pleistocene. Today, they occur only in bamboo forests in Sichuan, Shaanxi and Gansu Provinces, ranging over a total area of about 13,000 km². Census data acquired in the mid- to late 1980s placed the wild population at about 1000 individuals. New surveys concluded in 2002 placed its numbers at about 1600. A recent population assessment using DNA extracted from droppings suggests an even larger population. Approximately 200 pandas are maintained in **captivity**, primarily in China. This population has achieved remarkable growth within the last decade through improved breeding.

China regards the giant panda as a national treasure, and commonly refers to it as belonging to the world. Substantial progress in **conservation** has occurred in recent years as a result of collaborations with non-governmental organizations such as the World Wide Fund for Nature and several American zoos. Prior eras of gifting and short-term commercial loans to zoos internationally have given way to lending agreements that, in some cases, generate funds for conservation of the wild population. Cooperative international arrangements have been implemented to provide training in reserve management, community-based programmes and captive breeding. Added to these efforts, the Government of China is investing billions of dollars in replacing marginal farmland with forest and in upgrading programmes for protected areas. The number of panda reserves had been expanded from 14 in the early 1990s to a total of 56 by 2006.

Giraffe

Giraffe (*Giraffa camelopardalis*) are the smallest megaherbivores; adult males weigh an average of 1200 kg, while adult females average 800 kg. Giraffe live in sub-Saharan Africa, where they are usually found in savannah and riverine habitats, although in Namibia they survive in desert-like conditions. They are listed as conservation-dependent by the International Union for Conservation of Nature (IUCN) and are common wherever adequate habitat remains to support them, but decreasing in number over the past decade (except in South Africa). They are readily distinguishable from other animals by their height (as adults, males can be 6 m tall, while females are usually 4-5 m tall) and pelage. Spot patterns can be used to distinguish individual animals. Giraffe are ruminants in the order Artiodactyla, and share the family Giraffidae with okapi. Until recently, all giraffe have been considered members of a single species, but genetic work published in 2007 suggests that there may be up to six distinct species.

Giraffe reproduce throughout the year, and females become pregnant while still nursing their previous offspring. Among ungulates, species can be grouped into two types according to their maternal behaviour: **hiders** (in which young remain at a distance from their mothers, often concealed in vegetation) and **followers** (in which young remain close to their mothers at all times). Giraffe fall into the former category, with mothers spending time away from calves in order to: increase calves' cryptic; reduce the cost of protection for the mother; conserve calf energy and water; decrease calf heat loads; and enable the adult female to negotiate terrain that would be difficult for the calf. Initially, females leave calves lying out singly, but older calves often rest together in groups. Bonds between mothers and offspring are persistent (as long as 22 months), at least

P.287

until the next parturition. Females are observed in closer proximity to their mothers than to males in the second year of life, and some recent reports suggest that mothers and daughters may maintain bonds into maturity.

Feeding and ruminating account for about 80% of the daytime activity budgets of wild giraffe. They mainly eat *Acacia* and *Grewia* species that require them to use their tongue to obtain leaves while avoiding thorns and stinging ants. Giraffe feed for longer and eat different plant species during the dry season than during the wet season. Oestrous females reduce feeding time while engaged in mating activities, and pregnant giraffe eat higher-protein and higher-fat food resources than do lactating females.

Field studies have concluded that giraffe form only loose social bonds, and frequent changes in social partnership are typical (see: **Social flux**). However, defining a group of giraffe has been problematic because of the potential disparity between giraffe and human perceptual fields. Giraffe may use their

height and infrasonic (low-frequency) **vocalizations** to maintain contact over long distances, as has been reported for **elephants**. Therefore, group membership may be more consistent than previously reported. The population of females within a study area appears to be fairly consistent, while there is significant fluctuation in the male population. Social groups are more stable and larger when resources are plentiful, particularly in the wet season.

As in many ungulates, sociality differs by sex. Females with young calves live in nursery groups that are fairly stable in composition, and may form the basis for lying-out groups of calves. Bulls are likely to be found in social groups until they are fully mature, when they are typically solitary. Younger bulls frequently spar with each other, standing parallel and swinging their heads towards each other. Adult bulls occasionally spar, and rarely engage in intense fighting (which does not develop from sparring). Age and size are fairly good predictors of dominance among males, and larger, older bulls have a higher success rate in inducing females to urinate. By tasting and smelling a female's urine (**see: Flehman**), males can identify oestrous females and will perform **mating behaviour** with only those females in **oestrus**.

From a welfare perspective, the prevalence of **stereotypies** in captive giraffe may indicate a need for improvement in captive environments. Zoo-housed giraffe and okapi perform both locomotor and oral stereotypic behaviour; a survey found that 79% of the individuals performed at least one type of stereotypic behaviour. Licking of non-food objects was the most common form of stereotypic behaviour, reported in 72% of the animals in the survey. Over 29% of the giraffe and okapi paced and 3% performed other forms of stereotypic behaviour, which included **self-mutilation**, head tossing and tongue playing. Feeding motivation appears to be related to oral stereotypies in giraffe and okapi, while aspects of the physical environment predict locomotor stereotypies. These results corroborate research on domestic hoofstock.

In the zoo, giraffe are often fed hay and manufactured grain feed, with occasional browse. None of these foods is difficult to process and they are normally provided in open-topped feeders. At Zoo Atlanta (USA) and the Paignton Zoo Environmental Park (UK), experimental changing of feeding techniques caused repetitive licking to decrease dramatically, supporting the idea that motivation for feeding and/or **rumination** is related to oral stereotypy in giraffe. More research is needed to reduce the prevalence of stereotypic behaviour in the giraffe.

Glucagon-like peptide-1

Glucagon-like peptide-1 (GLP-1) is important in the regulation of blood sugar, appetite and food intake. Nutrient balance is maintained by inputs arising from gastrointestinal distension, intestinal hormones, nutrients present within the gut and in the blood following absorption. Nutrients in the gut trigger the release of GLP-1 together with other gastrointestinal peptides such as **cholecystokin** and ghrelin. There are two forms of GLP-1 produced but they appear to be equipotent in their effects, which include: stimulation of **insulin** and inhibition of glucagon release; inhibition of gastric emptying; reduction in gastric acid production; and suppression of food intake by stimulating a sense of satiety.

(DSM)

Glucocorticoid

Glucocorticoids are one of two types of corticosteroid hormones produced from the cortex of the adrenal gland, the other type being mineralocorticoids. Whereas the latter have a primary effect on salt/water balance, the former - as their name suggests - affect glucose metabolism, causing blood glucose to rise. These hormones are particularly associated with the **stress** response (**see also: General adaptation syndrome**). The most important glucocorticoids are cortisone and corticosterone, with one or the other being the dominant glucocorticoid, dependent on the species. Other effects of the glucocorticoids include anti-inflammatory and immunosuppressive effects, effects on **cognition** and a role in the maturation of the lung.

There are many synthetic glucocorticoid drugs (often referred to as **steroid hormones**) that are often used to control inflammation or immune-related conditions in animals, and these drugs (e.g. prednisolone, dexamethasone and betamethasone) are much more potent than the natural hormones. Side effects of these drugs include increased appetite and thirst, and their excessive use can result in iatrogenic (drug-induced) Cushing's disease. The cognitive effects of these drugs in animals that might affect welfare remain largely unknown.

(DSM)

P.288

Goad

The term 'goad' describes both an instrument, such as a flexible pole, stick or club, used to move animals on and the act involving its use. The principle behind the use of a goad is to apply negative reinforcement (**see: Reinforcement - types of**) to encourage the animal to move away from the goad in order to guide its movement; however, it is often used inappropriately by being applied without a clear **contingency** related to the animal's behaviour or with an inappropriate intensity that may cause the animal to panic. This gives rise to **welfare** concerns about its use. Electric goads (sometimes known as cattle prods or 'hotshots') are available that discharge an electric current when they come in contact with the skin of the animal. The use of the goad, together with other negative interactions with a **stockperson**, increases the risk of high lactate and cortisol levels and **PSE meat** in pigs, together with a more general avoidance of people.

(DSM)

Goal-directed behaviour

Goal-directed behaviour may refer to any behaviour or sequence of behaviours that is performed in order to achieve a perceivable goal. Goal-directed behaviour can be inferred by its reliable termination when the individual perceives specific stimuli that, by their presence, imply that the goal has been achieved. For example, **foraging behaviour** might cease when the individual perceives signals of satiety, **courtship behaviour** might cease when eggs are observed in the nest and **grooming** behaviour might cease when the irritation disappears. Frequently, observable events are used to infer the goal of a behaviour (and this may be subject to bias), although experimental behavioural studies may be used to assess the **motivation** towards certain goals more objectively.

Goal emulation

The phrase 'goal emulation' was first coined by Whiten and Ham (1992). They used it to refer to a type of **social learning** (i.e. a mechanism in which the observation of other individuals or the products of their activities facilitates or enables the acquisition of novel behaviour) (**see also: Observational learning**). Whiten and Ham intended the term goal emulation to refer to the same mechanism that was first described and labelled as plain 'emulation' by Wood (1989). Wood argued that children will not only attempt to imitate the form of others' actions, but also 'try to emulate them by achieving similar ends or objectives'. 'More specifically, emulation includes "instances where children achieve common goals to those modelled, but do so by using idiosyncratic means that were never observed"' (Whiten *et al.*, 2004). Whiten and Ham prefixed 'emulation' with the word 'goal' in order to distinguish it more clearly from **imitation** (i.e. learning to do an act by seeing it done), because 'dictionaries tend to equate emulation with imitation'.

Tomasello (1990) was the first person to discuss emulation with respect to non-human (animal) behaviour. When he first discussed the term, it is clear that he intended it to refer to (goal) emulation, as previously described by Wood. He stated that: 'A focus on the demonstrator's goal may lead the observer to be attracted to and seek to attain the goal. The observer may then attempt to "emulate" the demonstrator's behaviour, that is, to reproduce the completed goal by whatever means it may devise.' Hence, in contrast to imitation, when emulating, an observer learns about the goal of a demonstrator's behaviour, not the topographical details of the actions used. In other words, an emulator learns about the ends not the means by which others achieve goals.

For example, an observer chimpanzee sees a **conspecific** use a delicate twig to winkle termites out of their mound. The demonstrator slowly inserts the twig into a hole in the mound, gently agitates it from side to side for a few seconds and then slowly extracts it, revealing several guard termites that have attached themselves to the twig's surface. In this case, the goal is ingestion of termites. In contrast to imitation, if the observer were learning via emulation, it would learn nothing about the precise behavioural strategy employed by the demonstrator. Instead, the observer would be attracted to and seek to attain the goal (i.e. extracted termites) by whatever means it may devise. The observer may eventually

end up re-inventing, through its own independent problem solving, the same or a very similar fishing technique (especially if it is exposed to discarded twigs near the mound), but it might also hit upon a completely different strategy such as smashing down the mound through use of brute force. If it emulates rather than imitates, the observer learns nothing from watching the demonstrator about the strategy used (i.e. the fishing technique); instead it learns about, and its subsequent behaviour is directed by, the goal (i.e. attainable termites).

As Whiten and Ham (1992) acknowledge, the use of the word 'goal' in relation to emulation is cognitively loaded. It could be taken to mean that, when emulating, an observer attributes goals to the demonstrator. If characterized in these terms, emulation would constitute evidence of mental state attribution. Tomasello (1998) categorically refutes that he ever intended emulation to refer to a mechanism by which observers perceived a demonstrator's actions as goal-directed. An alternative, and much less cognitively complex, characterization is that observers can attend to results, and may consequently set goals for themselves that function to attain similar results. Whiten *et al.* (2004) argue that both characterizations of the term are valid. Hence, they distinguish result and goal emulation from one another and both are placed within the superordinate category of 'end-state emulation' (i.e. copying only the end or outcome of an action sequence).

Tomasello (1998) expanded the original meaning of emulation to incorporate observational learning about the properties of objects and the potential relations among them. As he explains:

It so happens that when I observe others manipulate objects I learn a lot about those objects and their affordances for my own actions much more than when I observe the objects sitting idle. Thus, if we give naïve chimpanzees a rock and a nut, they may not discover on their own how to crack the nut open. However, if they see another chimpanzee do it, they might learn from this observation that nuts can be opened, which creates a new possibility for them, and they might even learn something about the rock's role in the process.

P.289

Emulation thus characterized involves learning not about the behaviour used to manipulate objects, but about such things as an object's causal relationship with other objects or substances, that it might contain other objects or substances within it, its length, solidity, rigidity, function and so forth.

The ability to learn about the affordances of objects by observation is likely to involve highly complex cognitive operations. It may be equally, if not in some cases more, cognitively complex than imitative learning. Learning about the properties or affordances of objects seems a quite different process from learning about the results or goals of another's actions. Hence, Whiten *et al.* (2004) use the label 'affordance learning' (of properties, relations and functions) and distinguish this from end-state emulation.

In summary, emulation is a term that has come to mean different things to different people. Recently, many of the contradictions and sources of confusion have been clarified. It seems most helpful to follow Whiten *et al.*'s (2004) lead and distinguish end-state emulation from affordance learning. It also makes sense to distinguish between result and goal emulation. Result emulation is a relatively cognitively simple process in which observers attend to results and, consequently, set goals for themselves that function to attain similar results. Goal emulation is a process by which an observer 'regards the model (i.e. demonstrator) as an organism with goals and seeks to reproduce what it infers to be the model's goal on a particular occasion' (Whiten *et al.*, 2004). There does not seem to exist, as yet, any unequivocal empirical evidence of goal emulation in non-human animals.

Goat

Goats are ruminant animals, similar in size to **sheep**. Roughly 95% of the 765 million goats in the world are found in the developing countries of Asia, Africa and South America.

They have a well-founded reputation for eating a wide variety of feedstuffs. Similarly to other ruminants, they have a complex stomach comprising the rumen, reticulum, omasum and abomasum. The bacteria and protozoa found in the rumen and reticulum break down the foodstuffs, including cellulose and hemicellulose, which are fermented to shorter-chain fatty acids that can be absorbed from the rumen.

As do other ruminants, goats regurgitate and re-chew their foodstuffs, which increases the surface area for the microorganisms to work upon. This, in combination with the high concentration of microorganisms in the ruminal liquor, allows goats to survive on very low-quality, high-fibre feeds. However, for high levels of productivity and health, good-quality nutrition is essential.

Goats are agile animals, and indeed they often are found in trees. This allows them access to some of the most inaccessible feed. In combination with their ability to utilize low-quality feeds and relative drought tolerance, they can survive in conditions where sheep and cattle cannot.

Goat production

Goats are kept throughout the world for a variety of purposes. The commodities they produce include meat, milk, fibre, skins, horns and dung. Dung can be collected and used either for fuel or to fertilize household vegetable gardens. Goats are often more suitable for smallholder production (in both temperate and tropical situations) than cows, as their products are in more manageable quantities. Linked to this is another advantage - because more individuals can be kept (roughly five goats graze the same area as one cow), the risk to the farmer from losses due to disease, stealing, etc. is reduced. They are usually inexpensive to purchase and their fast reproductive rate means that herd numbers can build up

rapidly (to a level determined by the availability of feed). This can be particularly important after events such as natural disasters and war.

Goat meat is unlike pork and beef in so far as it is consumed throughout the world, and there are no religious taboos associated with its consumption. It is fairly lean and does not have the acrid, fatty smell produced when cooking lamb, and is thus more acceptable than lamb in many parts of South-east Asia, especially the Philippines.

Carcass yield is typically between 35 and 50%, similar to that for sheep (Steele, 1996). In young kids the yield is less, as the head, rumen and internal organs make up a greater proportion of the live weight than those of an adult goat. However, kid meat is highly valued, especially from very young (8-12 weeks) kids in the Caribbean and Latin America, where it is known as *cabrito*.

Carcass fat content, especially subcutaneous and intra-muscular, is typically less than lamb. Abdominal fat is greater, however, though with correct butchering this can be tailored to suit the consumer's requirements. Many breeds of goat are used for meat production, often as a by-product of a milk enterprise, though the Boer breed (originating from South Africa) is a developed meat breed with good carcass conformation and growth rates. These large animals have been exported throughout the world. Males weigh typically 130 kg and females 80 kg (Steele, 1996).

Goats' milk is also popular throughout the world. Its main advantage over cows' milk is that it has a higher percentage of small fat globules, which in turn means it forms a fine curd in the stomach. This allows it to be more easily digested by humans, notably those who are allergic to cows' milk. Chemical composition is very similar to cows' milk, however, though protein and total solids concentrations are slightly higher. This means that it is very suitable for use in cheese making. A number of breeds have been developed specifically for milk

P.290

production, the most important being the Saanen, Toggenberg, Alpine and Anglo-Nubian (females from these breeds are 50-65 kg in weight). With these breeds productivity levels are greatly improved, notably daily milk yield and the length of lactation. Unimproved tropical breeds typically produce 0.5-1.0 l/day for 125 days, depending on conditions and breeds, whereas specialist dairy goats in temperate intensive conditions can yield up to 5 l/day (Steele, 1996). In non-pregnant goats **lactation** can continue for up to 2 years, though production levels do decrease.

Products from goats' milk include fresh milk, cheeses, butter and ghee, and yoghurts. Cheese is particularly important in Western Europe (especially in France), where high-quality, niche products are highly valued by consumers. As a result, large, intensive flocks are found, complete with automated **milking** machines similar to those used to milk cattle.

Goat fibres are also highly valued, specifically Mohair and Cashmere. The former is a single coat of coarse, non-hairy fibre that is found only on the Angora breed. Its uses include furnishings, rugs and blankets, but the fine fibre from Angora kids is used in clothing. Cashmere is the fine-fibred undercoat found on a goat. Most breeds of goat have this, but not in sufficient quantities to make it economically useful. However, some breeds, such as the Kashmiri, have been developed over many centuries so that they have large quantities of this underwool. It can be spun in the same way as a sheep's fleece and is used for the production of high-value clothes.

Dietary requirements

Goats differ from sheep in one major way - they are browsers rather than grazers. Thus they exhibit a behavioural preference for foliage from trees and bushes in addition to grasses and plants. They have a well-founded reputation for eating almost anything, which can range from plant material through plastics to electricity cables. This means that care must be taken when looking after goats: fields must be

constantly checked for objects that may harm the animals if ingested, particularly if electric fences are used to control grazing. However, the positive element to this is that they can be used to clear overgrown land of weeds. As long as the area is fenced adequately, stocking rates of 10 goats/ha can be maintained on land to control and eliminate weeds (Steele, 1996). This works most effectively when the goats are moved in rotation around pastures ahead of cattle or sheep. The practice has been used in areas throughout the world, particularly in New Zealand, South Africa and the USA. Castrated males have proved to be the most effective in this respect, as they do not have the nutritional demands of pregnant or lactating females.

Goats' milk has a reputation in some quarters for having a tainted taste. In reality, this arises from a number of factors. First is the influence of diet, especially if a goat eats a shrub or weed such as ivy. In addition, certain feeds such as kale, turnip, swede, garlic and cow parsley can taint the milk, and should be avoided. Therefore, for milk production care must also be taken to prevent this from occurring and thus tainting the milk. Other factors that increase milk taint include genetic inherited traits, vitamin B₁₂ deficiency, **mastitis** and poor hygiene and milking technique (Hetherington and Matthews, 1992).

Typical feed dry matter requirements are 3% of the animal's body weight per day for meat production, 4-5% for dairy production in less developed areas and around 8% in intensive dairy systems. The grazing behaviour exhibited by goats is highly selective. Being agile increases their range of feeding options. Initially, when put on to fresh pasture they are unselective, but as their intake increases so too does their selectiveness. They graze individually rather than in flocks, often seen standing on their hind legs in order to reach browse from overhanging trees, and in some instances even climbing on to low branches.

As mentioned previously, goats are especially difficult to keep enclosed. They will easily escape from the majority of fences used to restrict cattle and sheep. Some will jump over, so fences of at least 1.2 m are necessary, though Steele (1996) suggests 1.5 m as a minimum height. Some individuals can wriggle and burrow under wires, so consideration must also be given to this aspect. Electric fences can be used, though if the goats are horned it is strongly advised not to use the net type of fence due to the risk of entanglement and subsequent death of the animal. Goats have the ability to learn how to operate latches and bolts, and so these must always be mounted in sites inaccessible to the animals.

Breeding

As with sheep and cattle, the practice of flushing (enhanced feeding and nutrition before mating) is highly effective at increasing conception rates and litter sizes.

Conception can be through either natural mating or **artificial insemination (AI)**, the latter depending on availability within an area as this is not as widespread as the use of AI in cattle, for instance. Goats are in **oestrus** throughout the year in the tropics but are seasonal in temperate areas, though less so than sheep. In many dairy goat herds, artificial lighting is used in spring in order to manipulate day length and thus have year-round milk production.

Gestation is typically 145 days, though kidding can be anywhere in the region of 140-150 days depending on various factors, including litter size - European breeds tend to be nearer 150 days; in Saanen it can even be a few days longer than this. The udder starts to produce and fill with milk prior to kidding (**parturition**), and in some goats a small amount may leak just prior to the birth.

Average litter sizes vary from 1.5 in breeds such as the Boer and Alpine to 1.9 in the Saanen, though these increase slightly with increased body size of the nanny and increasing age.

If vaccinations are administered 2-4 weeks before kidding, the protection will be passed on to the kid via high levels of immunoglobulins in the colostrum.

Health

In general goats are hardy animals, certainly more so than sheep. However, they do need veterinary care and consideration. Although somewhat resistant to illness, once ill their condition deteriorates rapidly. They are also particularly susceptible to pneumonia, mainly as a result of insufficient or poor-quality housing.

As a result of their inquisitive nature and willingness to eat anything, choking can also be a problem. Likewise, plant poisoning can be a problem under poor management conditions. Control of weeds such as ragwort is essential, though

P.291

most evergreen shrubs should be considered poisonous unless known to be otherwise, including rhododendrons, azaleas and laurels. Goats can browse members of the *Prunus* family (cherry, plum, etc.) but, although the fresh leaves produce no problems, the dry and wilted leaves are poisonous.

Their browsing behaviour also means that goats are more susceptible to internal **parasites** than sheep or cattle. Reasons for this again go back to their willingness to eat anything and browsing of feed that other livestock cannot reach. The four groups of internal parasites that infect goats are cestodes (tapeworms), nematodes (roundworms), trematodes (flatworms) and protozoa (unicellular organisms). The nematode species *Haemonchus contortus* is considered to be responsible for the vast majority of cases; it attaches to the wall of the abomasum and feeds off the blood of the animal. This loss of blood renders the affected animal anaemic and sluggish. Control of intestinal parasites in goats is very similar to that for other ruminants, and includes grazing management (resting pasture to decrease numbers of infective eggs and larvae), avoiding the grazing of wet and swampy areas, drenching with anthelmintics, and numbers within the digestive tract can be limited by the feeding of fodder and browse with a high tannin content.

Other conditions for consideration include foot-and-mouth disease, footrot, mastitis and enterotoxaemia. This latter **disease**, also known as pulpy kidney, is an acute, often fatal clostridial disease (*Clostridium perfringens* type D) arising from bacteria normally found in the digestive system and the soil. However, if there is a sudden change in diet, particularly if large quantities of cereals are fed, these bacteria multiply rapidly and produce the toxin that causes the condition. Thus it is vital that all changes in a goat's diet are phased in gradually wherever possible.

Vaccinations are available to lessen the risk and are highly recommended. Most enterotoxaemia vaccines also contain an anti-tetanus dose (*Clostridium tetani*), *which protects the animals against the possible fatal infection from the numerous scratches and pricks that result from their browsing behaviour.*

A good indication of an animal's general health is the nature of its faeces, and the goat is no exception. The dung should consist of small pellets similar to that of rabbits and sheep, and certainly not liquid in any way.

Housing

While in general goats are fairly healthy animals, they do need year-round **housing**. This need is exacerbated by cold and wet conditions, when goats become particularly susceptible to pneumonia. Good ventilation is essential to prevent this condition, though draughts at animal level must be avoided. Slatted floors are often used to prevent a build-up of dung and associated health problems.

Social behaviour

Goats are social animals, and it is a general consensus that they should not be grazed individually. Traditionally, however, many farms kept a single goat tethered away from the rest of the livestock. The

advice now is to always keep a goat with other animals, either other goats, sheep, cattle, horses or even donkeys.

Gonad

The gonads comprise the testes in the male animal, for which the term is most commonly used, but the term also encompasses the female homologue, the ovaries. In both sexes the principal function of the gonads is gamete production spermatozoa by the testes and oocytes by the ovaries - but in both cases there is an important secondary endocrine function. Gonadal hormones have regulatory roles in the processes of gamete production, but are also important for a wide range of other parameters linked to reproductive success, including cyclical changes within other parts of the reproductive tract and in the initiation and control of reproductive and **courtship behaviour** patterns.

Although there are significant differences between the testis and the ovary both in terms of morphology and function, there are also many underlying similarities, which is unsurprising as male and female gonads develop from a single undetermined bipotential primordium consisting of a mixture of germ cells and somatic cells. This primordium within the embryo is poised to activate one of two alternative developmental programmes in response to a sex determination signal early in the course of fetal development. The primordial germ cells can be identified at an early stage of development (day 7 in the mouse) originating at the base of the allantois at the posterior end of the primitive streak, where a small population of cells (approx. 45 in the mouse) is allocated to the germ cell line; these cells migrate to the genital ridge where they proliferate and aggregate together within the non-differentiated developing gonad. These primordial cells will become either, in the male, prospermatogonia in a state of mitotic arrest or, in the female, oogonia arrested in meiosis I.

In addition to the germ cells there are somatic support cells partitioned with the germ cells within the seminiferous tubules in the testis or within follicles in the ovary. These are the Sertoli cells in the male, the first cell population to undergo determination, and the follicular cells or granulosa cells in the female. Thirdly, there are endocrine somatic cells, the testicular Leydig cells or ovarian thecal cells, which are steroidogenic cells located in the stromal tissue of the testis and ovary. Each of these three

types of cells in the early embryo has bipotential and can form either male or female cell types within the morphological architecture of the testis or the ovary.

In mammals the choice of developmental pathway to testis or ovary is dependent on genetic factors in the form of specific genes present on the Y chromosome, although in other vertebrates other trigger systems may operate, with many **reptiles** for example utilizing environmental cues and allocating sex

P.292

according to egg incubation temperature. Ovarian formation is considered to be the default condition that occurs in the absence of activation of testis-determining Y chromosome genes in mammals; however, the completion of the ovarian pathway must also involve its own specific genetic factors.

In both sexes, the gonads have an important role in fetal development. In 1947 Alfred Jost demonstrated that rabbit fetuses castrated *in utero* all developed female genitalia irrespective of whether they were genetically XX or XY, thereby demonstrating that expression of the male reproductive phenotype is dependent on the presence of the fetal testes. In both sexes steroid hormones from the fetal gonads supplement the endocrine function of the maternal-placental unit. Some species, for example the horse, show a period of pronounced gonadal hypertrophy during development, so that the gonads are for a time the most significant structures within the fetal abdomen, before subsequently regressing to the much smaller size seen in the neonate.

The male phenotype is dependent on the secretion of two testicular hormones: first, anti-Müllerian hormone (AMH), produced by the Sertoli cells and responsible for degeneration of the Müllerian ducts, the precursors for the female tract; and, secondly, the steroid **testosterone**. Testosterone, secreted by fetal Leydig cells, initiates differentiation of the Wolffian duct into the epididymis, vas deferens and seminal vesicles, and causes the urogenital swellings to develop within the scrotum and penis. In females, **oestrogen** secreted from the fetal ovaries appears sufficient to induce the differentiation of the Müllerian duct into its various components - the oviducts, uterus and cervix - while in the absence of androgen support the Wolffian duct regresses.

This developmental role for the testes *in utero* is concluded at **parturition**, and endocrine activity of the gonads largely ceases with steroid hormone production maintained at very low levels until puberty is reached. This juvenile hiatus may not be evident in small, short-lived mammals that tend to reach puberty early but, in larger mammals, the delay to puberty may ensure that important growth and maturation processes are completed before reproductive function begins. At puberty gametogenic and steroidogenic activity in the gonads is stimulated by rising levels of hypothalamic and pituitary hormones, particularly resulting from release of **gonadotropin-releasing hormone** (GnRH) from the **hypothalamus**. The trigger for resumption of GnRH production remains to be fully elucidated, but it is clear that its timing can be influenced by environmental factors such as **photoperiod** and by aspects of nutritional status. GnRH stimulates the release of the gonadotropins **follicle-stimulating hormone** (FSH) and **luteinizing hormone** (LH) from the **pituitary gland**. These hormones are identical in males and females, and the steroidogenic cells within the gonadal stroma (Leydig cells in the testis and thecal cells in the ovary) are receptive to LH while the supporter cells within the germ cell compartment (Sertoli cells in the testis and granulosa cells in the ovary) are sensitive to FSH. In response to raised gonadotropin levels the gonads increase steroid production, which has effects on both the activity of the gonads themselves and a series of secondary systemic effects establishing the secondary sex characteristics.

Gonadal morphology does differ between the sexes. The adult testis has a connective tissue capsule, the *tunica albuginea*, and a parenchyma packed with finely coiled seminiferous tubules lined by the germinal epithelium with a mixture of germ cells and Sertoli cells. Spermatogenesis occurs within the germinal epithelium, with developing spermatozoa moving progressively from the tubule wall to be released into the lumen as they complete their maturation. From the seminiferous tubules newly created sperm are collected in the *rete testis* and transported from the testis into the epididymis for further maturation and

storage. The endocrine Leydig cells are situated in the interstitial tissue between the seminiferous tubules. The cells of the tubule walls, together with a ring of Sertoli cell-cell junctions, combine to form the blood-testis barrier, which makes the tubules an immunologically privileged site, shielding haploid spermatozoa from autoimmune attack. Seasonal breeders may show changes in the size of the testes between the breeding and non-breeding seasons, these changes being directly related to the level of sperm production and, in many livestock species, measurements of testicular size have traditionally been used as an indicator for fertility assessment.

The adult ovary has a fibrous core surrounding a parenchyma containing numerous primordial follicles, each containing a single oocyte within a layer of granulosa cells. The number of these primordial follicles is effectively fixed during fetal development, and the pool of follicles is progressively depleted throughout the animal's breeding life. During the breeding season cohorts of follicles are recruited to begin a process of growth and maturation that culminates, depending on species, in the production of a single or small group of ovulatory follicles ready to release their oocytes into the oviduct of the female tract for fertilization. Interstitial tissue surrounding the follicles contains the endocrine thecal cells, which act in association with the granulosa cells to produce oestrogen in the follicular phase of the cycle and subsequently **progesterone** in the post-ovulatory luteal phase.

Initiation of gametogenesis may be regarded as 'physiological puberty', and the presence of spermatozoa in the ejaculate - or follicular growth and ovulation - means that these animals are technically fertile; however, in many cases it is not until the secondary sex characteristics - gender-related characteristics not directly affecting the reproductive tract - are fully established that animals exhibit their complete reproductive behavioural repertoire. For example, males may need anabolic steroids to increase in size and strength or to develop other endocrine-dependent structures in order to attract females or compete with other males. With some large mammals this may mean that successful breeding may occur only some time, even years, after gonadal competence is achieved.

In mammals, gender identity and related gonadal morphology are fixed in the course of fetal development and, while some genetic conditions or other developmental problems can result in ambiguous or otherwise non-functional gonads, these conditions are generally permanent and not alterable in later life. However, this is not the case in all vertebrates, so, for example, some species of fish will demonstrate serial hermaphroditism in which reproductively functional female animals may, in response to environmental or social cues, change their sex and become functioning fertile males. Hermaphroditism is common in invertebrate species but, despite the dual potential of the vertebrate primordial gonad, does not appear to be a common evolutionary choice in these animals.

P.293

The single bipotential primordium responsible for both testis and ovary means that both originate at the same fetal site adjacent to the developing kidneys. However, while the ovaries remain abdominal throughout life, the testes in the large group of Boreoeutherian mammals (a clade of placental mammals) undergo migration to become situated in the scrotum, a pouch of skin in the inguinal region outside the main body wall. Migration occurs in two phases: (i) a transabdominal phase usually occurring approximately halfway through the gestation period, although precise timings vary with species; followed by (ii) an inguinal-scrotal phase where the testes pass through the inguinal canals, bilateral openings in the abdominal wall, into the scrotum. The fetal testes are attached to the abdominal wall by a ligamentous structure, the gubernaculum, which, as the fetus grows, remains the same length, having the effect of drawing the testes down away from their origin in the mesonephric region. The reason for the scrotal position of the testes in this group of mammals has long been the subject of debate. Migration is a complex and highly regulated, androgen-dependent process that is generally completed by, or soon after, birth. In cases where migration fails and the testes remain within the abdomen, termed cryptorchidism, a

not uncommon condition in **companion animals**, pigs, horses and humans, although rarer in cattle and sheep, spermatogenesis is compromised and the animals are infertile.

The scrotal position means that the testes are maintained at some 3-4°C lower than core body temperature, and the importance of this temperature difference is emphasized by a number of other thermoregulatory adaptations. The scrotal wall has little insulation associated with it either in terms of hair, fur or fat layers, and a slip of muscle within the spermatic cord, the cremaster muscle, allows the scrotum to be held close to the body wall under cold conditions or to be lowered away from the abdomen when environmental temperatures rise. In addition, the main testicular artery supplying the scrotum is highly coiled and is in close association with a network of testicular veins to form an efficient counter-current heat exchange system in the so-called pampiniform plexus, which cools arterial blood as it leaves the abdomen and simultaneously re-warms returning venous blood. While this small temperature difference appears necessary for spermatogenesis in this group of mammals, a number of mammalian species and all birds retain abdominal testes with normal fertility, while in some other species there is a temporary migration of the testes into the scrotum during the breeding season followed by withdrawal back into the abdominal cavity in the non-breeding season.

From the earliest recorded times the gonads have been known to affect aspects of behaviour. **Castration**, or removal of the gonads, most commonly the testes of the male, has been extensively used as a method in livestock husbandry for reducing male-male aggression and territorial behaviour, making male animals generally more tractable and eliminating or reducing unwanted displays of sexual behaviour. Castration is also used in **production animals** as a method of increasing growth rates and also to avoid undesirable flavouring in meat such as boar taint in pork. Regulatory effects on behaviour are endocrine-based and must be considered as unsurprising, as the function of the gonads is to coordinate appropriate and timely behavioural responses in order to facilitate the production, delivery and combination of competent gametes and thereby ensure reproductive success.

(MRC)

Gonadotropin

Gonadotropins (also called gonadotrophins) are hormones that are so called because their first identifiable effects were on stimulating the gonads. The gonadotropins include **luteinizing hormone (LH)** and **follicle-stimulating hormone (FSH)**, both produced by the anterior **pituitary gland**, and chorionic gonadotropin, produced by the placenta during pregnancy. **Stress** has a differential effect on pituitary gonadotropin production, depending on the nature of the stressor; for example, acute cold or **heat stress** causes an increase in LH but does not cause a rise in FSH, but, if prolonged, the level of both hormones may fall as the pituitary gland biases activity towards the production of adrenocorticotrophic hormones over gonadotropins, the process and consequences of activation of the former resulting in suppression of the latter. The differential production and release of gonadotropins by gonadotroph cells in the pituitary arises as a result of the actions of a range of hormones, including activin, inhibin, follistatin and the sex steroids (see: **Oestrogen**; **Testosterone**).

Gonadotropins can be used artificially to induce ovulation or superovulation in females for embryo transfer, but there is not necessarily cross-species compatibility. For example, mares do not respond to the gonadotropins of other species, and even equine FSH can be unreliable in its effects.

Gonadotropin-releasing hormone (GnRH)

GnRH (also known as luteinizing hormone-releasing hormone (LHRH) or luteinizing hormone-releasing factor (LHRF)) is released in a pulsatile pattern from cells in the **hypothalamus** into the portal blood stream, where it has its primary effect on the gonadotropic cells of the anterior **pituitary gland**, which produce **follicle-stimulating hormone (FSH)** and **luteinizing hormone (LH)** - both forms of **gonadotropin** as a result. In females, the frequency of the pulses varies with the **oestrus** cycle, whereas in males it is more consistent. The amount of GnRH produced varies with the plane of nutrition and the maturity of the individual, being very low in the undernourished and prior to sexual maturity, resulting in the suppression of sexual activity and infertility at these times. Immunization against GnRH can be used as a form of non-surgical **castration** (chemical castration) in some species such as pigs.

Gorilla

Gorillas are the largest living primates. Males may reach 275 kg in body weight in the wild and stand up to 1.75 m tall; females are considerably smaller, reaching on average 100 kg body weight. Until recently there was thought to be only one species of gorilla, *Gorilla gorilla*, with three subspecies ranging from the mountains of eastern Africa through central Africa to Nigeria. However, recent molecular and morphological studies

P.294

have confirmed that there are two gorilla species, each with two subspecies: (i) the western lowland gorilla, *G. gorilla*, from much of western and central Africa (including the critically endangered Cross River gorilla, *G. g. diehli* from Nigeria and Cameroon); and, 1000 km away, (ii) the eastern gorilla, *Gorilla beringei*, with two subspecies, the mountain gorilla (*beringei*) of the Virungas of Rwanda, Uganda and Democratic Republic of Congo (DRC) and the Impenetrable Forest in south-western Uganda, and the eastern lowland gorilla (*graueri*) in eastcentral DRC.

Western and eastern lowland gorillas inhabit lowland tropical rainforest, but Cross River and mountain gorillas are found in montane (highland) rainforest and bamboo forest up to an altitude of 3500 m.

Gorillas are mostly terrestrial foragers, especially the montane subspecies, but females and juveniles may be arboreal, using suspensory **locomotion**. Silverback male western lowland gorillas may also climb large trees. Locomotion on the ground is usually quadrupedal, and typically involves knuckle walking, but gorillas may stand and even take a few steps bipedally, especially when foraging on aquatic plants in bays (swamps). Being diurnal, gorillas sleep at night. They do not have a **core area** where they rest (although their **home ranges** may have a core area that is used more intensively), but make nests of whatever vegetation is available where they have been foraging. Nests are usually constructed in trees, particularly for the mountain gorilla; for some western lowland gorillas nests may mostly be built on the ground.

Up to 22 **vocalizations** have been recorded from gorillas, including long-distance hoots that can be heard up to 1 km away, aggressive roars and growls, and barks and grunts to encourage coordination of the social group. The most dramatic form of **communication** is the chest-beating display, particularly of adult males, which occurs when strange gorillas or even humans approach too near. The display begins with some hoots, then the gorilla stands bipedally and beats its chest alternately up to 20 times with slightly cupped hands, and finally the gorilla runs about on all fours, dramatically breaking vegetation.

Gorillas have highly stable social groups comprising usually an adult, silver-backed male, which dominates several females with their dependent young. Other black-backed younger males associate often temporarily with the group before moving off to live alone for a few years, before returning when mature to try to take over or establish a new group. Group sizes range typically from two to 34 individuals in all subspecies of both species. In some mountain gorilla groups there may be more than one mature male that may associate for up to 10 years. These multi-male groups usually contain closely related males such as fathers and sons or brothers and halfbrothers. Even so, these males have weak social relationships with each other and are competitors for mates. Non-breeding males may also form groups until such time as they take over or establish their own groups, and here the relationships are more amicable.

Owing to the high stability of a gorilla social group, all young females leave, usually voluntarily, to join a neighbouring group or to establish a new group with a young silverback thus avoiding inbreeding. Some females move between several groups, but in other groups females may cooperate to prevent incoming females joining that group. In mountain gorillas any young transferring with a female are almost invariably victims of infanticide, whereas this has not been observed in eastern lowland gorillas. Some multi-male groups split to found new single-male groups. Although most gorilla social groups are as described above, in some parts of western Africa fission-fusion **social systems** have been observed, which may reflect local availability of sparse food resources spread widely over large home ranges. When two gorilla groups meet they may: ignore or avoid each other; interact amicably for a while; or there may be open hostility, particularly between adult males.

Gorillas breed throughout the year. Females have a menstrual cycle like humans and other great apes, which lasts 27-28 days, with peak fertility lasting 1-3 days in mid-cycle. Although it is usually the dominant silverback that mates with all the breeding females within a group, females do select mates when opportunities arise, such as when two groups meet or in those groups where there is more than one adult male. Gestation ranges from 251 to 295 days (mean 258 days), and the single young weighs about 2 kg at birth. Twins have been recorded, but are very rare. The young are weaned at 3-4 years, so that a female may only give birth every 3.5-4.5 years. In accordance with the predictions of the **parental investment** theory, female mountain gorillas appear to invest more in the rearing of male young, as shown by higher and slightly increasing levels of **grooming** throughout infancy and generally later weaning.

Western lowland gorilla group home ranges range from 7 to 23 km², with a high degree of overlap between groups, whereas mountain gorillas' ranges are only 4-11 km², also overlapping but rarely at the same time. Groups travel 148-5500 m/day while **foraging** and their diets can comprise up to 100 plant species, as has been recorded for eastern lowland gorillas. Mountain gorillas feed on more than 50 plant species, of which about three-quarters are vines, herbaceous plants and parts of trees, including leaves, bark, stems and roots. Western lowland gorillas have equally diverse diets, but these tend to include more fruits (e.g. 40%). Gorillas have a keen sense of smell and are able, for example, to reject overripe fermenting fruits. They also develop complex manipulative skills for dealing with this wide range of foods, but do not use tools.

Granivore

Granivores are animals that eat seeds as the main part of their diet, and can be found among both vertebrate and invertebrate species, especially mammals, birds and insects. Granivory can be divided into pre-dispersal seed consumption and postdispersal seed consumption, and these different types of consumption require different **foraging behaviour** strategies. Some plants have evolved defences, such as toxic tannins, to defend themselves against granivores, while some granivores have co-evolved adaptations to these plant defences.

(LMD)

P.295

Grazing

Grazing is a method of **feeding** and, in particular, relates to the cropping and ingestion of growing grasses. The grazers are predominantly the mammals, and common examples include **rabbits**, kangaroos, **horses**, donkeys, **cattle** and **sheep**. Grass is also eaten by snails, slugs, grasshoppers, tortoises and geese. Natural grasslands often develop as a consequence of insufficient rainfall to support forest and are largely made up of perennials that propagate by lateral stems that spread beneath the soil surface and produce a mat of vegetative shoots. Regular grazing can act to preserve and improve the grassland, as cropped leaves continue to grow and new grass growth is higher in nutrient content.

The structure of the mouth and jaw influences how the herbage is cropped. Horses gather plants into their mouth using the sensitive prehensile lips and cut through the tough, fibrous stems using their upper and lower incisors, whereas cattle and sheep have no upper incisors, but have instead a horny pad that acts as a cutting board for the lower teeth. For example, cattle graze herbage by collecting it into the mouth and compressing it against the upper palate with the tongue and lower incisors. The herbage is then severed from the plants by jerking the head upwards. This is repeated several times a minute, typically 30-70, and the animal moves its head from side to side as it walks. Associated with grazing bites are occasional chewing bites or manipulative movements of the tongue or lips to manoeuvre the herbage in the mouth. These are more common when the herbage is long and fibrous. Sheep and **goats** feed more selectively than cattle due to their smaller mouthparts and are able to nibble at the shortest of grass due to their split upper lip. Cattle therefore cannot manipulate individual plant items to the same degree as sheep and goats.

To effectively digest the useable nutrients locked up within the rigid plant cell walls, grazers must first (using the molar teeth) grind down the plant matter into smaller fragments. Ruminants regurgitate food into the mouth, where it is further ground down by the molars ('chewing the cud'). This increases the available surface area for enzymatic digestion and microbial fermentation. Proteins, lipids and soluble carbohydrates are broken down by enzymatic digestion. No mammalian enzymes are capable of breaking down the structural components of plant cell walls. Cellulose is one such structural component, and many herbivores depend upon it as a major energy source. Instead, symbiotic microorganisms that live within the digestive tract are able to break down the cellulose and other structural components to organic acids through the process of fermentation. Microbial fermentation occurs in specialized and enlarged chambers that are located either in or near to the foregut or the hindgut. Ruminants are foregut fermenters, whereas rabbits and horses are examples of hindgut fermenters.

To cope with a nutritionally variable environment, grazers adopt a patch-feeding strategy whereby preferred plant communities are regularly visited and sampled. Thus selection of grazing sites is not uniform across the whole pasture due to both positive selection of desirable areas and avoidance of undesirable areas. For example, selection occurs across the surface of the pasture (horizontal selectivity); within any pasture there are tall areas of herbage close to faecal deposits that are left ungrazed. The rejection around each faecal deposit will be greater in undergrazed swards because animals have the choice of other, clean areas to graze. Herbage around dung deposits is rejected initially because of the smell of the faeces, and later because of its maturity. Typically it is lighter and browner than 'grazed' green herbage, and this indicates that it has a low nutritive value. Whereas darker green pastures are usually preferred because this indicates higher nitrogen content, dense pastures are preferred because they give a greater bite weight.

Selection also occurs within the depth of the forage canopy (vertical selectivity). When determining the height above ground level at which to defoliate the sward, grazing animals probably balance a high leaf: pseudostem ratio (which would maximize nutrient content of the herbage) with achieving an adequate total intake. According to optimal foraging theory, the composition and volume of the plant eaten and the energetic cost of grazing are optimized by the animal to supply its nutrient requirements at least cost.

The grazing action of cattle allows them to select a greater proportion of leaf material than the sward contains as a whole, thereby increasing the digestibility of their diet. This is primarily because they graze the upper strata of the sward (i.e. above the pseudostems, normally about 2 cm above the soil surface), and this layer contains more leaf material. However, cattle do not exclusively graze tall swards and leave short areas untouched. When offered a choice of 3- or 6-cm grass swards, cattle spend only just over one-half of their grazing time on the tall sward. Horses have also been noted to reside significantly longer on patches of long grass that had been mown to a height of 15 cm. Sheep, on the other hand, select individual tillers - shoots that sprout from the base of a grass - and sever them much closer to the ground than cattle, providing less frequent but more severe defoliation. This has its effect on the sward itself: because of the reduced frequency of defoliation, more tillers escape grazing altogether and become rejected due to their maturity, especially if the stocking rate of the sheep is too low. With cattle this usually occurs only in herbage around dung deposits, and even this is limited if the stocking rate is high. This ability of cattle to keep a pasture relatively free from mature herbage has led to their sometimes being kept principally to defoliate mature pasture on hill sheep farms. There are even greater advantages if cattle and sheep actually graze together, as the sheep do not show an aversion to cattle dung deposits and will prevent herbage near it from becoming mature and wasted. The sweeping side-to-side grazing action of each individual animal combines with the cohesive grazing action of a group of grazing animals to result in a sward that is all, or nearly all, defoliated to a common height, with the exception of areas around dung deposits. Herbage height largely determines the bite size or mass, with a tall sward giving the greatest ease of prehension and therefore minimum foraging time.

In a mechanistic model of the grazing process, the feed intake can be determined from the grazing time multiplied by rate of intake. The latter can be further subdivided into bite mass and rate of biting, and the bite mass determined from the herbage density and bite size or volume. Bite volume is the product of the bite area and bite depth. Bite area is a function of palate breadth and the distance between the palate and the tongue when the mouth touches the sward. Bite depth is the main factor regulating the other behavioural factors, and it is

P.296

largely determined by sward height. Hence, on a 10-cm lush spring pasture, intake rate of cattle is about 25-30 g dry matter (DM)/min, whereas a 5-cm autumn pasture will only be eaten at a rate of 15-20 g DM/min.

The useable energy gained from plants is far less than from animal protein, and thus large grazing mammals have to spend much of their time feeding in order to acquire sufficient daily nutrients and

energy. For cattle, the maximum grazing times and biting rates normally occur at about 10-12 h/day and 65-70 bites/min, respectively, although longer grazing times of 13 h/day have been recorded on sparsely vegetated rangeland. This gives a normal maximum of 50,000 bites/day, although individual cattle achieve more. High-yielding cows may have to balance the requirement for long grazing times with the requirement for adequate lying and ruminating times. This emphasizes the need to minimize the time that high-yielding cows are kept off the pasture for milking. Grazing lactating dairy cows typically have about five meals per day, each lasting on average 110 min. Cattle with lower intake requirements in relation to their weight (e.g. dry cows, mature bullocks) have fewer and shorter meals. Normally, the first meal begins shortly after dawn, followed by two to three meals between morning and afternoon milking, and the longest, most intensive meal in the evening ending around dusk. This is to provide sufficient food to digest during the night period. There is often a short meal averaging 30 min at about 01.00, after which the rest of the night is spent ruminating and resting.

The horse, as a hindgut fermenter, has a slightly different digestive strategy from the ruminant and compensates overall by having a higher voluntary intake and rate of gastrointestinal passage. Free-ranging horses spend 13-18 h each day grazing and browsing, and similar total foraging times of between 15 and 18 h have been recorded with pastured horses. In general, horses take regular grazing bouts throughout each 24 h period, although time of day affects bout length, as longer feeding bouts have been recorded at dawn and in the late afternoon.

Grazing is a very important commensal system ecologically between plant and animal, allowing both to thrive while maintaining good utilization of land and other resources.

(CJCP)

Great ape

The great apes or anthropoid apes belong to the superfamily Hominoidea, whose living representatives include the **orang-utans** (*Pongo* spp.), the **gorillas** (*Gorilla* spp.), the **chimpanzees** (*Pan* spp.) and humans (*Homo sapiens*). Until recently humans were regarded as being sufficiently different from the other great apes that they were assigned to separate families, the Hominidae for humans and the Pongidae for the great apes. However, recent molecular studies have confirmed the very close relationships between all the great apes and, today, all are regarded as being hominids, or with only the orang-utans remaining in the Pongidae.

Being phylogenetically so close to humans, there has been a vast amount of behavioural research aimed at all great apes, both in the wild and in captivity. This research often helps us to directly or indirectly gain some insight into the behaviour and **ecology** of our now extinct ancestors. The great apes show a spectrum of closeness of relationship with humans, from the distantly related orang-utans to the most closely related chimpanzees and bonobos. Comparison of behaviours, cognitive abilities, **social systems** and ecology provide us with interesting insights into how australopithecine and early *Homo* may have evolved and which factors (and in what sequence) were most important in the evolution of our own species.

Non-human great apes all inhabit tropical forests, including rainforests, montane (highland) forests and woodland savannah. Unlike us, the other great apes are more arboreally adapted, ranging from the orang-utans, which move mainly by suspensory climbing, to the more terrestrial gorillas, which typically move quadrupedally by 'knuckle walking'. Intermediate between the gorillas and orang-utans, chimpanzees and bonobos move around and forage both on the ground and in the trees. Orang-utans are mainly fruit eaters, but gorillas feed mainly on leaves, pith, shoots and other herbaceous vegetation, although western gorillas feed more on fruit than eastern gorillas. Chimpanzees and bonobos feed mostly on fruits, pith and nuts, but also consume leaves, invertebrates, birds' eggs and small vertebrates. However, adult

males may hunt cooperatively to kill larger prey such as **monkeys** and duikers, which are shared among the group members.

Social systems are very different between the non-human great apes. Adult orang-utans are normally solitary, the only consistent social groupings being when male and female come together for mating and mothers with their dependent young. This social system is also found in nocturnal prosimians and is termed a **noyau social organization**. Despite this apparent solitary social system, orang-utans have overlapping **home ranges** and are able to communicate and maintain a wide but dispersed social network. Fierce battles may occur between adult males, but younger males forage with females for weeks or months at a time. Although both males and females may become sexually mature by 7 or 8 years old, it may be many years before adult males become fully mature and are able to mate with females. Dominant males may suppress the social and physical maturation of subordinate males, who only develop fleshy cheek pads at full maturity.

Gorillas are the largest living apes and, like orang-utans, display considerable sexual dimorphism, with males weighing up to three times as much as females. Gorillas live in social groups of about ten individuals, led by a dominant silverback male with several females and their dependent young. The group may also contain one or more younger black-backed males. Mountain (*Gorilla beringei beringei*) and some western gorilla (*Gorilla gorilla* spp.) groups remain very cohesive, although with overlapping home ranges with those of other groups, but some western gorilla groups have been observed with a **fission-fusion social system**, whereby small groups split off and rejoin the main group when foraging, perhaps reflecting their typically larger home ranges with more dispersed foods. Gorilla society is unusual among primates in that males and females may move between social groups and the relationships are relatively weak between unrelated adult females, but are strong with the dominant silverback.

This pattern contrasts with the complex and dynamic social groupings of chimpanzees (*Pan troglodytes*), which have a fission-fusion social system. Interactions between group members are frequently noisy, boisterous and aggressive. Within a common shared home range, individuals may forage alone and come together temporarily to interact socially. Adult

P.297

males are usually gregarious, and their **dominance** within a hierarchy may depend on their social skills and the presence of brothers or close allies, as well as their age or physical attributes. They often patrol their home ranges, and hunt and forage together. Among females the strength of relationships may vary geographically; in eastern Africa females forage more solitarily and have weak social bonds and interactions with other females, whereas in western Africa females are more social and often forage together. Although undoubtedly all great apes develop local traditions or cultures relating to aspects of their behaviours and ecology, chimpanzees show a very wide range of local influences and traditions on almost every aspect of their social lives, including **communication**, social dynamics, tool use, etc.

Mating systems also vary from consortship (i.e. a male and female going off together), through mate guarding within the group to promiscuity. What particularly marks out chimpanzees from other great apes is their use of tools, which are used to process tough foods (e.g. nuts) and reach inaccessible resources (e.g. water or termites). All great apes build nests from vegetation at hand in order to construct a bed for sleeping at night. Nests are usually in the trees, but mountain gorillas rarely climb trees and build theirs on the ground. Chimpanzee home ranges are aggressively defended by males, which tend to be closely related to each other, thereby ensuring long-term and stable communities. In contrast, females move between groups to avoid inbreeding. Bonobos (*Pan paniscus*), on the other hand, are far less aggressive, and even though their home ranges overlap with those of neighbours, inter-group relations seem to be mostly peaceful. Like chimpanzees, bonobos have a fission-fusion social system, but males and females form mixed-sex foraging groups. Relationships between females are also much stronger than those between female chimpanzees, but give way to stronger male-female affiliations in larger foraging groups. Amicable interactions between bonobos often involve sexual behaviours, including copulations between

males and females, and genito-genital rubbing between females. Bonobos use larger food patches annually, which appears to be related to the greater social cohesiveness of the sexes.

Being so closely related to humans, the great apes have been subject to a vast amount of behavioural research, often in laboratories or captivity, since the second decade of the 20th century. The earliest experiments involved simple **discrimination** tests, which tested the ability of chimpanzees, in particular, to discriminate between shapes and colours of objects, and problem solving, such as how to use objects to reach inaccessible food items. A whole array of more or less complex experiments have been devised to elucidate our understanding of the **memory** and cognitive skills (**see: Cognition**) of all great apes, and much publicity has been generated in those few individual chimpanzees and gorillas that have been taught various forms of non-vocal **language** in order to communicate with humans and other apes.

(ACK)

Grooming

Grooming is a natural behaviour, and its function is thought primarily to be cleaning of the outer surface of the body, including removal of both dirt and **parasites**. Grooming may, however, be equally important as a **display behaviour** and a **social behaviour**. Many species of animals spend a large part of their time self-grooming. Grooming involves cleaning the surface, also known as the integument, of the body, including hair, skin, feathers or scales. As the integument may function as a temperature regulator, a sense organ, a protective device, a moisture barrier and a signalling device, its care is critical in body maintenance.

Animals differ in their methods of grooming. Mammals tend to lick themselves, use their teeth to nibble and/or use their forepaws or, in the case of primates, their dextrous hands, to rub and manipulate their hair. Companion animals may spend a large amount of time in self-grooming. Cats are known for their fastidious attention to self-grooming. Birds use their bills to realign and dress feathers with oil from a gland at the base of the tail, a behaviour known as **preening**. Invertebrate animals also spend time in grooming rituals. Insects rub their antennae, while crustaceans have appendages with setae (hairs) specialized for grooming. Like the insects, they keep their antennae and gills clean.

Licking the body surface may help to keep animals cool, and behaviours such as **dust bathing**, commonly observed in birds, may help with this process, too, as well as with the removal of parasites. In birds with a deformed beak or bill, the resulting parasite infestation can reduce the insulating properties of the plumage.

Grooming may also help to heal wounds. Ants have metapleural glands, located on the thorax (the region between the head and body of arthropods), which secrete antibiotic substances that are smeared over their bodies to keep bacteria and fungi from flourishing in their nest. Animal saliva may produce proteins that help in wound healing.

Grooming can also serve as a social signal. Small male rodents groom not only to keep their fur clean but also to attract females. The longer a male grooms himself the more interest a female shows, possibly due to the odours that the males are emitting. In some birds a ritualized display of grooming is often part of a male's courtship display, a bright and healthy coat attracting potential mates. In the chimpanzee males groom one another more when females are present. Social insects also use grooming as a communication tool. Worker honeybees groom the queen, picking up a pheromone that is then transferred through the nest.

The grooming of one individual by another is known as **allogrooming**, and will often be reciprocated by **conspecifics** in bouts of mutual grooming. Allogrooming is commonly observed between mother and

young, and is necessary for the cleaning of juvenile animals, which may not yet be able to toilet or self-groom.

Mutual or social grooming is readily demonstrated in adults of many animal species. Horses regularly groom one another, a response that has been shown to reduce heart rate. Primates, particularly the apes, help to remove parasites and dirt from one another's coats. Cats that are familiar with one another or related are more likely to groom one another and to spend time in proximity to one another. Birds, too, may groom one another, especially when forming pair bonds. Primate relatives, such as baboons and chimpanzees, spend more time grooming near-relatives than more distantly related individuals. This mutual grooming, therefore, serves not only to clean areas of

P.298

the body that are difficult to reach, but also reinforces the bond between kin.

Studying this intraspecific mutual behaviour can help scientists to understand the social systems of animal species. **Dominance** hierarchies (**see: Hierarchy**), for instance, may be determined by observing grooming interactions. Some scientists have taken this one step further and hypothesized that social grooming, as a **communication** tool, may even be linked to human **language** development. Where animal groups, such as some human societies, are large, it is difficult to maintain effective communication among all members by grooming, and language may have developed as a similarly effective way of communicating. In both grooming and speech, endorphins are released.

Grooming may be a less pleasurable activity when it is demonstrated excessively. This is a common behaviour problem in some cats and dogs that lick themselves excessively, resulting in hair loss, damaged skin or infection. Proximal causes of such over-grooming include itchiness from parasites, such as fleas or other foreign bodies on the coat, skin allergy or disease. Boredom and frustration have also been postulated as possible causes of this becoming a stereotypic behaviour. Excessive grooming may also be a product of anxiety, and the presence of an unknown feline in the vicinity may be enough to set off an excessive grooming episode in some cats.

Cases of over-grooming may require treatment in the form of anti-inflammatory or anti-anxiety medication, as well as rigorous attention to flea treatments, environmental change and behaviour modification. When licking is excessive, companion animals can be discouraged with the use of an Elizabethan collar, but this sort of intervention does not address the cause and can lead to further frustration.

Wild animals in captivity may also display excessive grooming behaviour, possibly as a result of boredom or frustration resulting in displacement behaviour, replacing more appropriate behaviour that may have been performed in the wild. Stereotypic or compulsive and repetitive grooming behaviour has been observed in many species, including giant pandas, parrots and chimpanzees. Behavioural enrichment programmes, now included in the management programmes of many zoos and wildlife parks, are helping to reduce this unwanted behaviour.

In addition to reducing the parasite load and keeping the animal's coat healthy, grooming, such as stroking or petting the animal for pleasure, is a mutually beneficial exercise and an important part of caring for animals, and therefore has a significant role to play in enhancing the human-pet bond.

Group

Animals are often found in close associations or groups. The study of why animals group together is a fundamental question in **sociobiology** and **behavioural ecology**. Animals may be brought together in groups by some localized resource or attraction, such as moths around a light or animals surrounding a water source in the desert. These groupings are not necessarily due to the animals being social in nature. If an animal's habitat and resources are locally distributed, they may overlap with other animals and these animals may then be found in clumps or groups. Additionally, if the habitats and resources of animals are patchy in distribution then the animals may also appear to be living in **social groups**, even though they do not engage in much **social behaviour**. Nonsocial animals tend to have random patterns of distribution and thus do come in contact with each other from time to time. Social animals, however, tend to have even or clumped distributions, which keep animals at the correct distances from each other, and they maintain those positions during specified time periods.

Animals may group together to gain advantages over living a solitary life. The strongest selective pressure to live in groups is thought to be protection from predators. Predators may hesitate to attack a large group of animals and, even if they do attack, the risk to any one individual of the group is greatly decreased. Groups of animals also have better access to resources, as a larger number of individuals are available to search for the resources; they potentially have access to mates without prolonged searching and they may have help in finding and/or building shelter.

(LMD)

See also: Grouping

Grouping

Animal associations are observed when groups are more beneficial for individual members than solitary action or existence. Predator mobbing is an example of a group-related benefit. Grouping may be distinguished into aggregations (e.g. an association of animals without any clear organization over an abundant source of food) and **social groups**, characterized by some degree of cohesion and coordination of movements among group members.

Growth hormone (GH)

Growth hormone (also called somatotrophin or somatotropin) is a polypeptide anabolic hormone produced in a pulsatile pattern by the anterior **pituitary gland** affecting cell growth and division, particularly within the musculoskeletal and immune systems. Overproduction results in accelerated growth, while underproduction during development can result in pituitary dwarfism.

From a production point of view, growth hormone is of interest because it increases food conversion ratio, lean muscle mass, bone mineralization and milk production. However, its use in animal production is controversial. Transgenic species can be produced that mature much more quickly and efficiently (e.g. growth rate in salmon may increase 11-fold), but there are concerns about the **welfare**, ecological and potential food safety implications of this. The exogenous administration of growth hormone is advocated by some and

P.299

opposed by others, with the administration of bovine somatotropin in dairy cows being licensed for use in **cattle** in the USA, but banned within the European Community on welfare grounds following a report from the EU Scientific Committee on Animal Health and Animal Welfare in 1999, which concluded that its use was associated with an increased risk of foot disorders, **mastitis** and reproductive problems. Advocates for its use have more recently suggested that, by increasing efficiency, its use can help to reduce the environmental impact of the industry used to support the feeding of cattle (e.g. production of fertilizers and feedstuffs), as well as reducing methane and carbon dioxide emissions from cattle, which are a significant source of greenhouse gases and global warming.

Growth hormone production follows a diurnal pattern, with surges occurring during the day and especially during **sleep**. The production of growth hormone is affected by the balance of specific stimulatory and inhibitory release factors (e.g. **growth hormone-releasing hormone (GH-RH)** and **growth hormone-inhibiting factor (GH-IF)**), which are produced alternately in the **hypothalamus** to magnify the pulsatile pattern of GH release, less specific factors (e.g. ghrelin, which has a stimulatory effect, and **oestrogen** and **corticosteroids**, which have inhibitory effects) as well as other physiological factors, such as levels of blood sugar, dietary protein, sleep and exercise. Negative feedback on production also occurs in relation to circulating levels of growth hormone and growth hormone-like factors such as **insulin-like growth factor**. **Stress** has a variable effect on growth hormone levels, with both a decrease (in response to **social stress** associated with overcrowding in rats) - but more typically an increase reported. This rise blocks the effect of **insulin** and helps to maintain higher blood glucose levels in preparation for action (**see: General adaptation syndrome**).

Growth hormone-inhibiting factor (GH-IF)

GH-IF, also known as growth hormone-inhibiting hormone (GH-IH), somatotropin release-inhibiting factor (SR-IF) or somatostatin, is a peptide hormone produced in a pulsatile pattern within the **hypothalamus** that is secreted into the portal blood supply, from where it is carried to the anterior **pituitary gland**, and stimulates the production of **growth hormone (GH)**. GH-IF appears to have wider direct physiological effects, such as suppressing digestive function, and its production may be suppressed during suckling (**see: Nursing**), although these effects are less consistent.

(DSM)

Growth hormone-releasing hormone (GH-RH)

GH-RH, also known as growth hormone-releasing factor (GRF or GH-RF) or somatocrinin, is a peptide hormone produced in a pulsatile pattern within the **hypothalamus** that is secreted into the portal blood supply from where it is carried to the anterior **pituitary gland** and stimulates the production of **growth hormone** (GH). Production in the hypothalamus alternates with growth hormone-inhibiting factor, which has an antagonistic effect on growth hormone production, resulting in the latter being produced in more marked surges and troughs.

(DSM)

Growth rate

Growth rate is most often measured as weight (or mass) gain over time. A common production measure, growth rate allows producers to assess flock/herd productivity. Growth rate curves, in conjunction with additional flock/herd information such as feed efficiency, can be used to determine the ideal time to market an animal. Growth rates are also used to compare strains or breeds and to compare production between years or seasons. Although there is a heritable component to growth rate, there is also a large environmental component. Growth rate is affected by numerous factors including diet, **stress**, immunocompetence and genetics. Growth rate is an ideal measure for assessing the production efficiency of new diets and genetic lines. With environment held constant in experimental paradigms, growth rate is often used as a measure of stress or stress-coping ability between animals of different strains, breeds or treatments, but should not be used as a stand-alone determinant of an animal's welfare. Animal production research has accelerated the growth rate of production animals over the past half century through improved breeding, nutrition, veterinary care, production practices and the use of pharmaceuticals.

Although growth rate varies greatly between and within species, it is most often a logarithmic function. Animals experience the most rapid growth in the time immediately following birth or hatch, and experience a gradual deceleration of growth rate. A plateau in growth rate is usually achieved around or shortly following puberty. Although animals may continue to gain weight following puberty, there is generally a slow rate of growth. In many cases animals that have passed their sexual maturity exhibit a reduction in weight or negative growth rate. Negative growth rates are also associated with injured or diseased animals. Egg-laying-type hens also exhibit a negative growth rate during the induced moulting period.

Guinea pig

The guinea pig, *Cavia porcellus*, comes from South America and does not originate from Guinea or Guiana. The 'pig' part is thought to derive from its resemblance to a suckling pig, and 'guinea' as a result of the countries visited by the trading vessels in the South Americas and Africa. In the 16th century the Dutch

introduced it into Europe where it failed to gain acceptance as a food, but it did as a **pet**. From there it was used as a research animal and to diagnose tuberculosis in humans.

Habit

A behaviour or sequence of behaviours that has been performed with such regularity in response to a certain stimulus, or at certain times, that it has become a fixed, semi-automatic response. The performance of the behaviour may occur with some regularity and may appear to be independent of its original reward. Habitual behaviour becomes entrenched within the behavioural predispositions of the individual following repetition, and this developmental element distinguishes it from fixed action patterns. Habits are often referred to in a negative context, although they may not necessarily be detrimental to the individual's welfare or fitness. For example, habits might include successful ritualized behaviour sequences, as occur, for example, in courting displays, as well as behaviours with more negative connotations such as stereotypical pacing within confinement.

Habituation

Habituation is a form of learning found widely in animals, including many invertebrate phyla. It is said to have occurred when the presentation of a previously arousing **stimulus** no longer elicits a response. Thus, it can be defined as learning *not to respond* to a stimulus. Behaviourally it may be very similar across phyla, but clearly different processes are involved in different types of habituation; for example, habituating to a noise is not the same as habituating to a toe pinch (which may be organized at spinal level). This emphasizes an important behavioural principle - similar phenomena may operate through very different mechanisms in different contexts. Habituation can improve biological fitness, since to respond to every novel or alarming stimulus, regardless of its significance, may waste energy and thus be maladaptive. The process and rate of habituation are dependent on three features of the causal stimulus: its nature, frequency and regularity. For successful habituation, a stimulus must be presented well beyond the point of habituation in order to minimize the risk of **spontaneous recovery**. Spontaneous recovery describes the rebound in response strength when a stimulus has undergone extinction or habituation.

Both domestic species and captive wild animals habituate to the presence and activities of humans and other species, as well as to their surroundings. This is also evident in behaviour development, when a puppy, kitten or foal quickly adapts to a novel environment. Livestock that live beside a railway line soon become accustomed to the visual and auditory stimuli of passing trains. Furthermore, ridden animals,

such as **horses**, donkeys, camels and elephants, show remarkable habituation to riding paraphernalia, such as saddlery. The early stage of exposure to the girth strap is sometimes difficult in horses because of their strong innate flight response to touch in the regions associated with the girth. However, habituation occurs when their innate predator-removal mechanisms, such as bucking and rearing, do not result in the removal of the girth pressure and so are not negatively reinforced. Forced exposure to a harmless stimulus is sometimes used in behaviour therapy, where it is often referred to as '**flooding**' or 'stimulus flooding'. Given the dangers of severe expressions of the flight response and its resistance to extinction, flooding should be used with care and progressively at the lowest threshold of fear. Habituation differs from the **extinction** of a learned response, as it is an instinctive response that is being eliminated, rather than one that has been previously conditioned.

Preventing the animal's legs from moving by means of hobbles during exposure to aversive stimuli has been employed for centuries by horse trainers. In this process, the animal is restrained with one or more legs trussed, and with the animal sometimes thrown to the ground. The horse is then exposed to repeated maximal presentations of aversive stimuli until it no longer responds. The mechanism relies on an emerging stimulus-response relationship that trains the redundancy of leg movement during presentation of an aversive stimulus (i.e. the animal acquiesces in the presence of that stimulus). There may be some evidence of stimulus **generalization** here, too, in that trainers often report a diminution of general aversive reactions as an outcome of such procedures, but such exposure may simply be inducing a state of **learned helplessness**. In the past, police horses have been hobbled to train them to habituate to various aversive stimuli that they might encounter in their work. The folklore of **horse training** (and some modern 'horse whisperers') often claims that the process is one of hierarchical intervention, that the animal quietyens because it accepts the dominance of the trainer and subsequently learns to 'trust' the trainer, but this is a misrepresentation of its scientific basis.

In other habituation procedures, the flight response may still be exhibited, yet complete escape is thwarted, for example in the 'round pen' training technique championed by Monty Roberts and many others interested in 'New Age' horse training. Here the animal is generally presented with an aversive stimulus in the form of human aggression (e.g. the trainer may be at the centre of the round pen flailing a rope at the animal while it runs around in flight). Because escape is impossible,

P.302

the animal's flight response is never reinforced and its motivation to flee may diminish, i.e. the response becomes habituated. Then, as the horse slows down, the human may become passive and relatively non-threatening, providing negative reinforcement of the habituated response. The trainer then shapes the horse's response so that the animal will gradually approach. Adherents to these methods claim great success in reforming previously traumatized horses. However, there are safety and **welfare** concerns surrounding this procedure, despite claims that it is more 'welfare friendly'.

Gradual habituation is a more common form of desensitization procedure, where the aversive stimulus is generally maintained at a low threshold until the animal habituates. For example, thunder-phobic dogs may be gradually exposed to mild recordings of thunderclaps. The intensity of the thunderclaps is gradually raised until the dog becomes habituated to thunderclaps of typical intensity.

During ontogeny, captive animals should be progressively habituated to the presence of humans and other potentially aversive stimuli.

Hamster

Hamsters are mainly nocturnal and live naturally in burrows in dry, rocky or brushy, steppe-type ground. There are several species of hamster: the Golden or Syrian hamster (*Mesocricetus auratus*), the European hamster (*Cricetus cricetus*), the Chinese hamster (*Cricetulus griseus*) and the Djungarian hamster (*Phodopus sungorus*). They are used in the laboratory and as pets. The most common laboratory hamsters are derived from *M. auratus*, which has a grey belly and a reddish brown coat. This species is thought to have been introduced to the Western world from a few pairs caught in Syria in 1930.

(DBM)

Handling

The handling of animals can be defined as the manual or mechanical carrying, moving and/or transportation of fauna. The correct handling of animals is important for their **welfare**, as incorrect handling may result in **stress** and **injury** to the animal. It may also have health and safety implications for the handlers involved.

Animals differ in their acceptance of handling by humans. Exposure to humans from an early age (**socialization**) generally makes animals more amenable to handling. Exposing and bonding animals to humans from an early age, otherwise known as **imprinting**, was first demonstrated in goslings and is important in a number of animal species, particularly birds.

There is often a specific time period during the early part of an animal's life in which acceptance of humans occurs. Such **sensitive phases** have been identified in **companion animals**. During this time period or age range, which reflects the sensory and motor development of the animal, particular events are likely to have long-term effects on the individual's development. In puppies, the sensitive period for interspecific encounters is generally considered to be between 2 and 13 weeks of age, with a peak between 6 and 8 weeks. In kittens it is between 2 and 14 weeks, with a peak between 2 and 7 weeks. During this time positive experiences with humans will tend to ensure a long-lasting and pleasant association with handling. **Aversive** experiences will be remembered and handling avoided. Similarly in **horses**, intensive handling of young foals supposedly results in more tractable horses.

Animals with very little or no exposure to human contact during sensitive periods of socialization will be difficult, and often impossible, to handle. Such individuals are often referred to as **feral** animals.

Animals that are handled from an early age are often more confident than those not exposed to regular human contact. In some cases, overly confident animals will challenge humans, which makes them more difficult to handle, especially if the challenging behaviour is reinforced. Knowledgeable and positive methods of handling should ensure that this does not become an issue.

Animals benefit from correct human handling throughout their lives. **Farmed animals** may be stressed by human contact when unaccustomed to it, leading to decreases in productivity, reduced reproductive performance and reduced immune function. Stressed animals may be more flighty, excitable, fearful or generally more difficult to handle and may also have lower milk production or poorer meat quality. High levels of **vocalization** in many species may be indicative of incorrect handling.

Handling that is inappropriate, inconsistent, clumsy or excessively firm may result in both acute and chronic stress responses, reflected in elevated plasma cortisol concentrations. Gentle handling decreases physiological stress responses and keeps animals calm and easier to handle.

Being unaware of the correct way to approach and physically handle animals can often compromise human safety and enjoyment of companion animals. Children must be shown how to handle both companion and farm animals. Young children must be supervised when interacting with animals, even small companion animals or pets, as either party may be injured or stressed as a result of a negative encounter. An animal, when lifted, should be supported by two hands. A child should be taught not to restrict an animal with strong holds, i.e. hugs, which are unnatural for the animal, especially when the animal is unknown to the handler. Handling with the use of species-appropriate **collars**, leads and harnesses should be encouraged.

Understanding animal behaviour and the behavioural ecology of the species can help to reduce stress levels in animals and make them easier to handle. Caution should be taken, however, as injured or frightened animals may become stressed, agitated and cause injury. Some animals may be less frightened in the dark, so covering them with a blanket may help with ease of capture and holding, especially when the animal is injured. Animals such as **cattle** may be frightened of dark or shaded environments, so provision of adequate, evenly distributed lighting may reduce **anxiety** in these animals. Approaching animals such as horses or **dogs** from an angle where they cannot see the advance may cause them to startle. Animals such as **cats** and **dogs** may respond aggressively to unseen approaches. Loud noises or some **odours** may also cause a fear response in some animals.

P.303

An awareness of the influence of rank on group movements may facilitate handling in production contexts. Herd animals, such as cattle, have a leader that they will follow and this can be used to the handler's benefit. By focusing on moving the herd leader, the whole pack can be encouraged to follow with relative ease. In contrast, when solitary, livestock may be difficult or even dangerous to handle and move. Some breeds of animals may be more reactive to human handling than others. More flighty or excitable breeds, strains or individuals may need more frequent handling by humans to get them acclimated to human touch and movement. When the animal is unused to human contact, entering its **flight zone**, the distance within which it will attempt to escape, may cause it to move away. Tame animals normally have a shorter flight distance (perhaps zero distance) than wild animals.

Animals that are to encounter humans rarely, such as livestock on large rural properties, should ideally still be exposed to human contact if they are to benefit at a later stage, when being loaded on to trucks, for instance, or when receiving veterinary treatment. Bruising and injuries lower productivity, and about half of all bruises are thought to be caused by rough, careless handling.

Aversive handling techniques are generally discouraged nowadays. Use of electric prods (**see: Goad**) for livestock and punishing collars such as check chains in dogs is decreasing in favour of more positive methods of handling. Understanding the animal's own behavioural repertoire and using motivators such as food are now considered superior to harsh punishment in handling animals.

Offering individuals a choice is often advocated as a method of enhancing an animal's welfare. For instance, when offered a choice of negative human contact (shouting and hitting) or positive contact (pail feeding), cattle chose the positive option. They also chose humans talking in a gentle voice as opposed to shouting. Positive interactions between stockpeople and livestock can influence their welfare and productivity.

The welfare of farmed animals and companion animals is of major concern to animal welfare and **animal rights** groups. The correct handling of animals can ensure their welfare, so it is important for all animal professionals to have an understanding of the correct techniques of animal handling.

Grandin, T. (2007) *Livestock Handling and Transport*, 3rd edn. CAB International, Wallingford, UK.

Hand rearing

Hand rearing is primarily required for orphaned neonates, but may also arise as an integral part of dairying and some **fostering** programmes (e.g. foals may be removed from their dams so that more valuable orphaned foals can be fostered). Capturing and hand rearing neonates can result in dangerous or flighty **wild animals**, and is common within the illegal trade in exotic animals (e.g. for pets and as street performers).

Hand rearing requires knowledge of each species' natural history, experience in the practicalities of hand rearing and a considerable amount of equipment (e.g. heat lamps and caging), which cannot easily be provided on an ad hoc basis. It is best performed by experienced specialist carers, and the first few hours of an orphan's time away from its parents are critical. Ill-advised feeding by inexperienced carers can prove catastrophic. Many countries have legislation that prohibits unlicensed personnel from hand rearing non-domestic orphans, a move that reduces the transfer of wild animals into the **pet** trade.

It is critical in neonates to avoid dehydration and to feed correctly. Hand-reared mammals usually need some form of immunoglobulin supplement to replace what would have been supplied by **colostrum**; colostrum hand stripped from a **conspecific** is usually fed. In the absence of colostrum from the same species, interspecific colostrum is better than none (e.g. goat colostrum can be given to lambs).

Birds are not fed specific immunological boosters, but their rations must be carefully mixed to reflect the sort of diet parent birds typically regurgitate for their young. Clearly, this depends on whether the parents are **carnivores**, **insectivores**, **granivores** or **piscivores** (e.g. raptor orphans need pulverized whole-body feeds because meat alone can rapidly cause an imbalance in calcium metabolism). Errors in diet formulation can lead to **starvation**, **malnutrition** and osmotic diarrhoea.

Experienced personnel are skilled in presenting food in ways that encourage the young to eat. Latex delivery teats are available in multiple sizes from veterinary suppliers. The frequency of feeding should mimic the **ethogram** as closely as is practical, which requires a serious commitment from carers, especially in providing night-time feeds for neonates.

Handling and **gentling** neonates may facilitate feeding and health checks but may not be entirely appropriate. Loss of **fear**, often interpreted erroneously as a loss of respect, may make animals dangerous to handle as juveniles. Furthermore, mal-**imprinting** may reduce the biological fitness of hand-reared animals when they are reintroduced to the wild. For example, filial imprinting may reduce an animal's fear of humans, increasing its chances of subsequent capture, while sexual imprinting on human carers may misdirect the courtship repertoire and reduce sexual **fitness**.

Ideally, hand-reared animals should occupy a physical environment analogous to that of a free-ranging conspecific (e.g. orphan joey kangaroos are generally kept in a bag like the marsupial pouch). An appropriate rearing environment can greatly increase success rates when young animals are reintroduced to the wild after weaning. Inappropriate dependence on shelter, for instance, may fail to prepare animals

for normal weather patterns in the native habitat. The company of conspecifics, especially for neonates, can be of critical long-term importance in social species, such as equidae.

Hand-reared animals should be weaned gradually at the time appropriate for the species. Their release into a captive social group of conspecifics or into the wild should be planned to maximize their chances of acceptance and minimize the risk of injurious **aggression or predation**.

Harms

Some systems of animal husbandry, animal **housing** and animal use cause animals to suffer in some way by imposing an environment or a manipulation procedure on animals that can

P.304

cause them **pain, distress** or other unpleasant feelings. Harms can be divided into two types: (i) those that are incurred to achieve an objective, end or a goal - i.e. the intended use of an animal, such as for egg or meat production - and may be the minimum needed to achieve those objectives (*necessary* harms); or (ii) more harm than the minimum necessary may be caused, even though that extra harm is not needed to obtain the accepted objective. In this case, where more harms than necessary are caused, they can be described as *avoidable* harms, and we have an ethical obligation not to cause them. For example, if **castration** of an animal is necessary for the best interests of that animal (e.g. testicular cancer) and if it is done without an anaesthetic or postoperative **analgesia**, then more pain and distress is caused than is necessary, i.e. that suffering was avoidable and so avoidable harms were caused.

Harrison, Ruth

Born 24 June 1920 and a graduate in English, Ruth Harrison developed great expertise in the methods used for the keeping and managing of farm animals. The publication of her book *Animal Machines* in 1964 changed the attitudes of many people and led directly to the Act of Parliament that protects farm animals in the UK. She commended efforts to increase food production but questioned the morality of keeping or treating animals in ways that were contrary to their biological functioning and gave them little opportunity to adapt, so that poor **welfare** resulted. She pointed out that the welfare of calves is poor if they are kept in small crates in which they could not turn around or groom themselves in a normal way, could not interact with other calves and received a diet lacking in iron and fibre - so the practice is cruel. She criticized the keeping of hens in battery cages and other systems for the intensification of animal production (see: **Intensification of animal production**). Indeed, she visited farms and spoke with experts on husbandry, biology and veterinary medicine until she was herself an expert. She kept up to date, presenting her knowledge to governments and others from the 1960s until a few months before her death in 2000.

Ruth Harrison read and understood scientific papers on farm animal welfare and sat on advisory committees such as **FAWC** and the Council of Europe Standing Committee of the Convention on the Protection of Animals kept for Farming Purposes. She would not allow inaccurate statements to go unchallenged, and politely reminded committee members of the necessity to focus on the welfare of the animals. She encouraged the scientific study of animal welfare and, as Chair of the Farm Animal Care Trust, promoted many new developments in animal welfare assessment and housing system design.

Head shaking

Head shaking is a condition involving recurrent, intermittent, sudden and apparently involuntary bouts of head tossing that may be so extreme as to throw the animal off balance. The term is most often used in relation to **horses**, and the condition may be so severe as to unseat the rider. Sneezing and snorting are frequently present, accompanied by attempts by the horse to rub its nose on the ground, a foreleg or nearby objects. Although the condition can occur at rest, more cases are obvious during exercise, especially at trot. Head shaking is not a diagnosis but a presenting complaint, and more than 60 disorders that may present as head shaking are now recognized, although establishing a diagnosis either ante- or post-mortem is often very difficult.

While a seasonal pattern of signs has been interpreted by some as a suggestion of an allergic rhinitis or condition linked to **photoperiod**, many other factors also correlate with the sunnier months of the year. These include an increased tendency to ride out, higher aerial dust burden, an increase in ozone, an increase in plant volatiles - such as those that are produced by linseed - and an increase in some moulds, any or all of which may result in irritation leading to head shaking.

The occurrence of certain specific behavioural features may suggest irritation of a specific area; for example, horses that shake their heads horizontally, either in addition to or instead of the classical vertical movement, or rub their ears, may be more likely to have a pain focus around the ears, such as might occur with ear mite infestation. 'Flipping' the nose, sneezing, snorting, 'clamping' the nostrils as if to close them and attempts by the horse to rub its face on a foreleg are all reported to be responses to naso-facial irritation or **pain**.

Since many cases remain without a definitive diagnosis or effective treatment, they may be labelled as a form of **stereotypy**, although a physical cause is suspected in the majority of cases, with increased attention focusing on the potential for referred neuralgic pain in the trigeminal nerve, which results in discomfort within the nose. This may be possible because many branches of this nerve are quite superficial and located close to riding gear (e.g. bit and bridle) that could cause damage. Because head shaking has a heterogeneous aetiology and a diagnosis is rarely made, treatment also remains problematic despite recent advances.

(DSM)

Headstarting

Headstarting is a **conservation** strategy in which juvenile animals, either bred in **captivity** or collected from the wild, are reared in a safe captive environment for varying lengths of time prior to release into natural habitats. The rationale behind headstarting is based on the observation that larger juveniles usually have a much higher probability of surviving the neonatal period than do smaller ones. If young animals can be reared in a captive environment free from predators and other threats of life in the wild, theoretically a greater proportion will reach sexual maturity and be recruited into the adult breeding population. Headstarting was initially applied to the recovery of declining sea turtle populations in the

1970s, and has since been adopted as part of integrated recovery plans for a number of other **reptiles**, including freshwater turtles, tortoises and iguanas.

Concerns have been raised that headstarting is not appropriate for all species and should not be used indiscriminately as a species conservation tool. In sea turtles, headstarting fails to address adult mortality, the major cause of population decline, and deprives the ocean environment of maturing turtles, which probably play an important ecological role in the marine food chain. For long-lived species with protracted developmental

P.305

periods, it may not be feasible or cost-effective to headstart enough juveniles to offset reductions in survival to adulthood. In contrast, headstarting appears suitable and effective as an interim conservation measure when applied to species for which severely reduced juvenile recruitment due to **predation** by invasive species is the major threat to wild populations.

Even when headstarting is feasible from a demographic perspective, animals reared in captivity for eventual release must possess the behavioural competency to survive and reproduce in the wild if **welfare** concerns are to be addressed and conservation benefits are to be realized. Minimally, release candidates must be able to locate refuges and avoid predators, acquire and process suitable food resources, locomote and navigate effectively on natural terrain, and interact socially in an appropriate manner with **conspecifics**. It should not be assumed that captive-reared animals, even those with apparently innate behavioural repertoires and without parental care, will be competent in a wild environment. However, it may be possible to enhance the competency of headstarted animals by combining species-specific training with a well-designed captive environment based on a solid understanding of the **behavioural ecology** and **ontogeny** of the species in question.

Some of the most successful examples of headstarting include programmes focused on iguanas in the Caribbean and the Galapagos Islands. The primary threat to these species is excessive predation on juvenile age classes by a variety of invasive species, including **feral** cats, mongooses, dogs, rats and pigs. Estimated remaining wild populations for several taxa are so low that emergency headstarting programmes have been initiated in an attempt to bolster recruitment while effective predator control efforts can be instituted. These programmes are successfully returning animals to the wild, and initial data on survival rates are promising.

Iguanas appear to be good candidates for successful headstart-release programmes for several reasons. They retain their natural wariness when carefully managed in captivity, are generalist herbivores that do not require extensive training in order to obtain and process natural foods and are capable of rapidly integrating into wild breeding populations. Nevertheless, it is likely that success might be further enhanced by providing experiences in captivity that familiarize release candidates with key elements of the specific natural environment into which they will be released. In particular, controlled experimental studies comparing post-release foraging abilities and growth rates of headstarted animals reared on artificial and natural diets would help elucidate the degree to which foraging competency can be improved through experience. Experimental studies focusing on the impact of exposure to simulated predators or predator cues on post-release survival would be useful in determining whether pre-release training programmes are likely to be cost effective. Comparative studies of post-release behavioural competency in animals headstarted in structurally simple and complex environments with and without exposure to conspecifics would also aid in the design of optimal captive paradigms. An especially promising area for future research is the use of artificial retreats with which animals are familiarized prior to release in order to encourage post-release settlement (**see also: Dispersal and habitat selection**).

Selection of a suitable release site and identification of appropriate release candidates are also important variables influencing restoration success that would benefit from further study. Comparative studies of headstarted animals released near to and far from known nest sites, into high- and lowdensity populations

and at sites experiencing greater and lesser degrees of habitat disturbance and human visitation would be valuable in teasing out the potentially interacting effects of these variables on long-term survival under a range of environmental conditions. Experimental studies to determine the optimal age and size at which to release headstarted individuals into the wild are another important component in developing a successful release strategy.

For several reasons, including considerations of behavioural competency, in-country headstarting programmes are preferable to those for which the captive phase is far removed from the release site. Locally administered programmes reduce the potential for transmission of exotic diseases between captive and wild animals, and allow headstarted animals to develop immunity to local pathogens prior to release. In-country programmes eliminate the stress of long-distance transport and allow release candidates to be reared in an environment where they can more easily be exposed to local environmental conditions, including predator and conspecific cues, natural food resources and local climatic conditions. Finally, on-site programmes can maximize opportunities for outreach, education and active involvement of local communities in restoration efforts.

Health

Health is a term that is open to multiple interpretations and definitions and, while many individuals have a specific concept of health, an all-encompassing definition is difficult to establish. Hence various approaches to defining health should be considered, including their limitations. Health could be defined

as 'the absence of **disease**'. An animal considered free of disease could be considered healthy but, conversely, if no disease is identified that does not guarantee a healthy animal.

P.306

To illustrate: faecal egg count levels can indicate a helminth infection of the gastrointestinal tract, but the animal may show no clinical signs of disease and could therefore be considered healthy. However, in the absence of a faecal egg count, it is also possible to have a high level of helminth infection with clinical signs. The difficulty lies in determining the point at which, in this case, the naturally occurring **parasite** infestation becomes clinically significant and thereby negatively affect the animal's health status.

In that context, disease can be defined as a 'sub-optimal performance of one or more body systems', with varying degrees of clinically apparent signs as a result of disease pressures and multiple system involvement. These body systems can include the gastrointestinal, reproductive, nervous, cardiovascular, immune, lymphatic, endocrine, musculoskeletal, integumentary and respiratory systems, separately or in combinations. Conversely, this definition can be used to define health as 'the status of performance of body systems and their interactions whereby poorer performance is usually associated with increased likelihood of clinical signs'. Based on this definition, the poor performance of body systems can result in a great variety of signs including those that are expressed through behavioural changes. Realistically, behavioural changes indicating decreasing health status are likely to be caused by one or multiple body systems functioning suboptimally or out of balance. A behavioural sign is not a diagnosis, as a given sign may arise from different causes (see: **Aetiology**). These competing explanations for the presenting sign form the basis of differential diagnoses. To illustrate, apparent avoidance behaviour in a cow could be due either to the neuropathy of BSE or the discomfort of trauma-induced pain. A depressed isolated animal could be suffering from a neurological disorder, toxic fever or could simply be ready for parturition.

(FLR)

Hearing

Selective pressures have resulted in different animal species having varying abilities to perceive sound. There are three main selective pressures determining hearing range for each species. First, the animal must be able to detect a sound. This ability allows an animal to determine the presence of soundproducing objects in its environment. Secondly, the animal must have the ability to localize the source of the sound, allowing it to react behaviourally and to either approach or avoid the sound source. Finally, the animal must be able to identify the sound and respond accordingly.

Assessment of the absolute hearing sensitivity of an animal (i.e. its ability to hear sounds of varying intensity) can be assessed using training and reward techniques. One procedure used to assess hearing sensitivity involves training a thirsty animal to touch a plate with its nose when it hears a sound. Correct responses are rewarded by the animal being given water. If an animal responds incorrectly (i.e. when no tone is present) the testing is halted for 5-15 s. Once an animal has been trained to respond reliably to hearing a sound, then sound intensity testing can follow. This is assessed by reducing the sound intensity until the animal does not respond. The ability of an animal to hear sounds of different frequencies can be assessed using a similar method. Testing can be performed until the animal has received sufficient water.

An animal's hearing ability is related to its specific requirements to survive. Birds have a relatively poor sensitivity and ability to perceive sounds of different frequencies. However, exceptions to this general rule include the pigeon, which is able to hear at low frequencies, presumably to assist navigation, and the barn owl, which has excellent sensitivity that assists it in locating prey during nocturnal **hunting**.

Mammals have a higher degree of variability in their ability to hear sounds. Unlike birds, they are generally able to hear sounds above 10 kHz, and some mammals - for example bats and porpoises - are

able to hear sounds above 100 kHz. Hoofed mammals have hearing abilities similar to that of humans, but are also able to hear ultrasonic sounds. **Carnivores** tend to be able to hear higher frequencies than hoofed mammals, with cats possessing the ability to hear sounds of approximately 79 kHz. The orders Rodentia and Lagomorpha are able to hear still higher frequencies, and the house mouse has been shown to hear frequencies of up to 92 kHz. Their lower frequency limit, however, is higher than that of other mammals.

The ability of mammalian vertebrates to hear ultrasonic sounds is due to the three auditory ossicles in the middle ear, which transmit sound from the eardrum to the cochlea. Nonmammalian vertebrates possess a single middle ear bone that is less effective in transmitting high-frequency sounds. Mammals also possess a pinna (the external ear). This structure acts as a filter and amplifies sound originating from in front of the focal animal while decreasing the amplitude of the sound originating from behind the ear. It also has the function of making the ear canal asymmetrical, i.e. the animal is able to distinguish between sounds originating in front of its body and sounds originating from behind.

The determination of the ability of an animal to localize sound is more difficult to assess, as localization ability is dependent on the specific sound being localized and the location of the sound source. The ability of an animal to accurately localize a sound source is increased in the horizontal plane compared with the vertical plane. Localization acuity is also increased when the sound source is located directly in front of the animal, and decreases at locations to the side of the animal. An additional factor affecting the ease of determination of localization ability is spectral composition. Broadband noise with an abrupt onset is easier to localize than narrowband noise. Some animals vocalize using pure tones, which are very difficult to localize, to make it more difficult for predators to establish the position of the individual.

There are two basic methods for determining an animal's localization acuity. The first is to assess an animal's 'two-point sensitivity' by training it to discriminate between the same sound presented from two loudspeakers and then reducing the angle between the speakers until the animal can no longer discriminate between the two. The second method examines the degree of error as an animal naturally orients its head towards the source when it hears a sound. Songbirds have been shown to have a threshold for separation of between 20 and 30°, hens have a separation of about 4°, while studies have shown that the barn owl can orient to a frontally placed sound with an average error of approximately 2°. The barn owl is thought to possess this degree of orientation accuracy to assist it in locating prey during darkness. The ability of mammals to accurately localize a sound source varies between species.

P.307

Elephants and humans have been shown to have a sound localization ability of approximately 1°, while cattle have been shown to have localization ability of only 25°. Some species are unable to localize brief sounds.

Upon hearing a sound most animals orient their head towards the source of the sound. It has been shown that the animal will direct the fovea of the eyes towards the sound to maximize the visual acuity in this area (**see: Vision**). Most mammals have a broad area of maximal visual acuity covering almost the entire horizon of the eye; this is known as the visual streak. These species, therefore, require less precise auditory information to locate the sound source.

(NC)

Heart rate

The heart rate (HR) is defined as the number of heart beats per unit time. Usually the unit time is 1 min, and thus HR is usefully quantified in terms of beats per minute (bpm). Activity within the cardiovascular system depends on input from the **autonomic nervous system** (ANS) as well as through local control mechanisms: cellular, metabolic, hormonal, receptor/reflex, etc. For the most part, HR is determined by the electrical discharge rate of the cardiac pacemaker (sinus node) and electrical conduction in other parts of the heart tissue. The behaviour of the sinus node is influenced by both divisions of the nervous

system that regulate automaticity and rhythmicity. Of most interest here is the extrinsic control exhibited by the ANS.

The sinus, or sino-atrial (SA), node is an anatomical region of the heart that is located in the epicardial groove between the right atrium and the superior vena cava. The node contains two types of cells, elongated and round. Of particular interest are the round, or pacemaker, cells that are capable of spontaneous depolarization that initiates electrical activation within the heart itself. In the absence of autonomic innervation or during complete autonomic blockage, the discharge rate of the pacemaker cells represents intrinsic HR. Initiation of a cardiac cycle primarily begins with the SA node, though the atrial pacemaker may also perform this role depending on local neurohormonal and neural conditions. Spontaneous depolarization within the pacemaker cells rapidly spreads across the right and left atria. Discharge rates within the pacemaker cells depend on ionic gradients and membrane permeability. Cardiac action potential in ventricular cells begins with a rapid increase in resting membrane potential (depolarization, phase 0), followed by a fall (phase 1) to a plateau (phase 2), and then a rapid return (repolarization, phase 3) to resting levels (phase 4). Sino-atrial and atrioventricular (AV) cells, however, differ during phases 4 and 2, giving rise to the pacemaker potential that is characterized by a progressive depolarization during phase 3 and absence of the plateau in phase 2.

Cardiac muscle is innervated through both the **sympathetic** (SNS) and **parasympathetic** (PNS) divisions of the ANS, through the cardiac plexus, with both divisions continually transmitting impulses: that is, they are tonically active. Intrinsic HR is, for the most part, slightly higher than that seen when PNS activity dominates, but varies according to the distribution of pacemaker cells with the node and the nature of transmembrane potentials. The ANS regulates cardiac activity by altering the discharge rate of the SA node or by changing conduction velocity in other areas of the heart. Action potentials are generated by both shifts in the concentration gradients of sodium (Na^+), potassium (K^+) and calcium (Ca^{2+}) across the cell membrane and ion channel permeability and the resultant cell electrical charges relative to its immediate environment. Ion channel permeability, which directly affects cell charge, is influenced by autonomic neurotransmitter signals. Parasympathetic nerve terminals release muscarinic acetylcholine, which alters ionic currents across cell membranes by increasing K^+ conductance. Administration of a muscarinic receptor antagonist, such as atropine, attenuates parasympathetic influences and results in an increase in heart rate as the ratio of sympathetic influence increases by default.

Parasympathetic nerves are located on the epicardial surface and innervate the heart wall themselves. Parasympathetic vagal nerves (left and right) innervate the SA (right vagus) and AV (left vagus) conducting pathways as well as the atrial muscle. Activity within the right vagus decreases discharge rate within SA cells, which slows HR, a negative chronotropic effect, and reduces conduction velocity by decreasing the force of cardiac contractions. Activity in the left vagus slows AV conduction of impulses from the atria to the ventricles. Too much parasympathetic control may cause several degrees (first to third) of AV block. Excessive AV blockade is harmful and is characterized on an electrocardiogram (ECG) by autonomously occurring P waves and QRS complexes. Extreme levels of PNS regulatory dominance can decrease HR in humans to as low as 20-30 bpm.

Parasympathetic nerve terminals release **acetylcholine**, which is rapidly decomposed by the enzyme cholinesterase that is present in large quantities in both the SA and AV nodes. The effects of alterations in parasympathetic regulation are both immediate and relatively short lived, enabling the PNS to exercise beat-by-beat regulation of cardiac activity. A further mode of influence is wielded by parasympathetic nerves that terminate on sympathetic nerves and impact on cardiac activity by inhibiting the release of sympathetic neurotransmitters. Left and right sympathetic (cardio-accelerator) nerves are distributed throughout the heart and form an extensive cardiac plexus. Left and right nerves have different influences on cardiac activity: left nerves are more concerned with inotropic (muscular contractility) conditions, whereas right nerves have more of a chronotropic impact on heart rate. Sympathetic nerve terminals

release the catecholamine **norepinephrine** (noradrenaline) that binds with β -adrenergic receptors throughout the heart, including the nodes, and has an excitatory influence on cardiac cell contractility and HR. Sympathetic regulation is somewhat slower than the nearinstantaneous parasympathetic effects. Exocytotic release of norepinephrine from the nerve terminal is thought to occur relatively slowly. Also, unlike parasympathetic acetylcholine mechanisms, a secondary messenger (adenyl cyclase) is involved, which slows the process down considerably. The result of this is a much more gradual alteration in cardiac activity, but it is one of extended duration relative to its parasympathetic counterpart.

Sensory regions, termed baroreceptors and chemoreceptors, located within some blood vessels (e.g. carotid sinus region, aortic arch) may also influence HR, based on the feedback of information concerning blood flow within certain vessels and its nutrient and gas content. However, higher cortical regions

P.308

of the **brain**, for example the thalamus, **hypothalamus** and forebrain - which are implicated in the expression of **emotions** - may override the more localized effects of these receptors, resulting in corresponding changes in blood pressure.

Heart rate has been widely used as a welfare indicator with the assumption that HR is increased when the animal is encountering stressful conditions. However, the difficulty in interpretation comes with the assignment of emotional state. In humans, it is known that HR can increase in pleasurable, exciting situations as well as during negative emotional situations. It is also influenced by purely physical factors such as **posture** and **locomotion**. For these reasons, there has recently been movement towards measures of cardiovascular function that may contain detailed information as to the relative inputs of the ANS (**heart rate variability**), and thus perhaps elucidate the emotional state of the animal.

Heart rate variability

Heart rate variability (HRV) is a measure of the beat-to-beat variations in heart rate. The time interval between successive heartbeats (interbeat interval, IBI) in healthy animals is not of fixed duration. Beat-to-beat variation occurs, reflecting the continuous interplay between ionic membrane currents responsible for sinus node automaticity, the **central nervous system** (CNS) and autonomic activity. Heart rate variability has attracted an increasing amount of attention over the last few years, as animal welfare scientists seek methods to obtain more information from cardiovascular data.

All physiological signals can be examined in both the time and frequency domains to separate the contributory frequencies that form the absolute signal. In cardiac research, both time and frequency analysis of cardiac activity are generically referred to as heart rate variability analysis. While the clinical importance of HRV was first recognized in the mid-1960s, the first research into these rhythmic variations was not published until nearly a decade later. This work emphasizes the inexactness of drawing inferences about the behaviour of the **autonomic nervous system** (ANS) from mean HR parameters. Different levels of activation in the discrete branches could potentially have the same consequence on cardiac activity,

i.e. identical mean HR. As the popularity of HRV research has increased, so too have the number and types of equipment capable of automatic and precise detection of IBI. It is now possible to obtain continuous **electrocardiogram** (ECG) information over a long period of time, such as 24 h, using ambulatory monitors.

Measurement of HRV

Numerous methods have been used to extract information from a time series of IBIs. There are a number of ways to analyse IBI data to gain information on autonomic activity: time domain methods, frequency domain methods and non-linear methods. Simply, time domain methods measure the parameters of HRV versus their time, frequency domain methods measure parameters versus their frequency and non-linear methods look at the complexity in the structure of HRV.

Time domain methods

There are several statistical approaches that may be used to evaluate heart rate variability in the time domain. These methods are essentially based on descriptive statistics and are perhaps the most straightforward way to manipulate IBI data. They can broadly be split into two categories: (i) measures derived directly from IBIs; and (ii) measures based on the difference between successive cycles. The simplest time domain measures to calculate are mean HR and mean IBI variables. Units for these variables are beats per minute (bpm) and milliseconds (ms), respectively. Additional methods derived directly from IBIs include standard deviation of normal-to-normal intervals (SDNN, also termed standard deviation of IBIs) and variance. The variance is simply the square of the SD and both are considered to be a good estimate of all components influencing overall heart rate variability. The mean of the standard deviation of all 5-min epochs within a 24 h recording (SDNNIDX) also reflects total variability, as does a coefficient of variance calculated by dividing SDNN by the mean R-R (as measured by ECG) interval length.

Analysis of measures derived from differences between successive cycle lengths is more involved than methods based on beat-to-beat intervals, but provides additional information about autonomic regulatory control. Several measures in this category provide good estimates of **parasympathetic nervous system** (PNS) regulation, including the root mean square of successive differences (RMSSD). This is calculated by finding the square root of the mean of the sum of the squares of differences between neighbouring beats. Parasympathetic activity can also be estimated by counting the number of interval differences of successive intervals that differ by a value greater than 50 ms (NN50). This measure, when divided by the total number of intervals, yields pNN50. All of these measures are highly correlated, not only with each other, but also with the amount of power attributable to the high-frequency variation on a power spectral density (described below), which in turn represents parasympathetic activity. Also, very high correlations have been shown to exist within measures by repeated monitoring of cardiac activity in individuals. Time domain indices are more easily calculated than frequency indices. They have been used extensively to assess cardiac function following myocardial infarction and have proved useful for assisting detection of those at risk of further life-threatening cardiac events and sudden cardiac death. However, their interpretation is restricted to inference about total variability and parasympathetic regulatory input only and they do not provide a measure of modulations in the sympathetic branch.

Frequency domain methods

The most commonly reported method of HRV analysis is that of frequency domain analysis. While time domain parameters are a good estimator of overall variability and variability attributable to activity within the parasympathetic branch of the ANS, they are less powerful than frequency domain

P.309

approaches and do not reliably quantify sympathetic control. There are two main approaches presently used to calculate the components of power spectral densities (PSDs): (i) nonparametric, Fast Fourier

Transformations (FFT); and (ii) parametric, autoregression modelling (ARM). Both approaches have their relative merits, with both describing the dynamic properties of the heart period signal similar to the way a prism decomposes light into its spectrum.

A spectrum is essentially a histogram that expresses the rhythmic components of the signal that it is decomposing. The FFT approach is extensively used in the assessment of secondorder rhythms in heart rate variability. FFT breaks any signal down into its constituent frequency components by partitioning the signal into different categories of variances that describe the different contributory frequencies that are contained in the signal.

The following two assumptions are made about data used in FFT analysis: (i) the data are discrete, i.e. the data series was created from a continuous sample that has not been spliced together from more than one source; and (ii) the data are stationary, i.e. their statistical properties (mean, variance, etc.) do not alter over time. Data generated from FFT can be visually presented using a PSD, which plots the amplitude (or power) of the component signals as a function of their frequencies. Spectral power for any frequency range is derived from the PSD by quantifying the area under the spectral curve at any given frequency band, for example 0.0-0.5 Hz. Typically, the Fourier approach is more appropriate for the analysis of shorter-term HRV (256 or 512 beats), as it is quite unusual for any biological signal to remain statistically stationary for any length of time. Consequently, longer segments of data usually violate the stationarity requirements needed to undergo FFT analysis.

While shorter windows of data exhibit greater stationarity, the resolution of their spectral estimates will be reduced. Although better resolution is achieved with longer segments of data, they are far less likely to meet the stationarity requirements to undergo FFT analysis. An alternative approach to FFT is ARM, which does not have the stringent stationarity laws of FFT analysis and so can be applied to longer signals. It can be used to analyse unequally spaced time series and has greater frequency resolution over FFT, making it more accurate for determining slow signals in short data series. For instance, to estimate low-frequency signals, FFT requires that the data contain at least one full cycle of the frequency of interest. ARM, on the other hand, requires just one-quarter of a cycle from which it can construct the full cycle. A further advantage of ARM over FFT is that it is less susceptible to spectral leakage. This occurs when power from one frequency component is not sufficiently separated from other frequency components, and is a common criticism of FFT. To reduce this leakage and further improve frequency resolution it is necessary to first 'window' data destined for FFT analysis. FFT, nevertheless, offers a distinct advantage over ARM - the relative ease of the actual computations involved - which, in part, explains its popularity among clinical scientists. As ARM fits the model to the data, prior information regarding the time series of the data is required in order to select an appropriate model/order. ARM, on the other hand, is a better analytical tool for decomposing extremely short segments of data and data where the statistical properties do not meet the assumptions required by FFT.

Interpretation of power spectral density

Early investigations on the PSD of cardiac IBI data, gathered during a variety of pharmacological, surgical and physical manipulations of the ANS, all highlight the presence of three principal spectral bands in humans, and later work has reported on their presence in other mammals. The precise location of these bands varies from species to species and may be predicted using respiratory rate and/or pharmacological interruption of the separate branches of the nervous system. The three bands are: (i) a high-frequency (HF) component; (ii) a low-frequency (LF) component; and (iii) a very low-frequency (VLF) component. In humans, these bands are centred around 0.25, 0.10 and 0.04 Hz, respectively. A fourth component, ultra-low frequency (ULF, <0.0033 Hz), is sometimes detected in spectra derived from longer-term recordings. Spectral components can be expressed as absolute values or as normalized units, where the discrete power bands are presented as a proportion of the total power in the spectrum. Normalizing the data gives a clear picture of the interplay in **PNS/sympathetic nervous system (SNS)** regulatory control, particularly

during recording when the total power is expected to fluctuate greatly. Normalized units, however, should always be presented alongside their corresponding absolute values to provide a complete picture of the autonomic activity under investigation.

An example of a pig-derived PSD, generated using FFT and showing the three principal components found in short recordings (512 beats), is presented in Fig. H.1. In humans, the VLF component is thought to

P.310

vascular mechanisms and thermoregulation, as well as activity within the renin-angiotensin system. The VLF component cannot be detected reliably in short-term signals by FFT analysis as they represent the much slower modulations in cardiac activity, and a single cycle typically takes longer to complete than the time available in a short signal (usually 5 min or 512 beats). Likewise, estimates of ULF are only statistically stable when obtained from long-term signals. In humans, this frequency band represents much of the power in 24 h spectra. It is thought to reflect neuroendocrine circadian periodicity, but the origins of the power in this band are presently not well defined.

Fig. H.1. Power spectral density of pig IBI data showing the location of the VLF, LF and HF power spectral bands and a prominent respiratory peak within the HF band. IBI, interbeat interval; VLF, very low frequency; LF, low frequency; HF, high frequency.

Of particular interest to animal welfare scientists are the LF and HF components that are known to reflect autonomic activity in humans, dogs, rats, pigs, horses and cattle. Power in the HF component is generated by respiratory modulation of parasympathetic (vagal) activity. The LF spectral component is mediated jointly by both sympathetic and parasympathetic regulatory activity. This has been determined experimentally in a number of studies using selective blockade or enhancement of one or both branches of the nervous system. For instance, atropine, a competitive antagonist of parasympathetic muscarinic cholinergic receptors that inhibits parasympathetic influences, diminishes all power in the HF spectral band while simultaneously reducing power in the LF band. Delivery of propranolol, a non-selective β -adrenergic (sympathetic) receptor blocking agent, causes a significant decrease in power in the LF band but power in the HF band remains unchanged. HF power has been found to exhibit a dose-dependent decline in magnitude following step-wise increments of atropine dosage. Such dose-dependent responses substantiate the sensitivity and reliability of using frequency domain parameters as estimators of autonomic regulatory activity. Complete blockade of both branches produces spectra with relatively no power, analogous to those seen in humans and animals following transplantation, due to an absence of innervation in the transplanted heart.

While estimates of sympathetic activity contributions to spectral power are more difficult to separate than parasympathetic input, a quantitative measure can nevertheless be obtained when specific information concerning HF power is available. As some PNS modulations emerge in the LF band, direct interpretation of LF power as SNS activity would in fact produce an overinflated estimate of the power attributable to sympathetic modulations. The LF:HF power ratio, however, can be used to quantify both SNS activity and sympathovagal balance. High values indicate a predominance of sympathetic regulatory control, whereas low values represent more PNS control. For instance, below 1 the ratio reflects parasympathetic dominance and, above 1, sympathetic dominance. A number of experimental manipulations have demonstrated how the LF:HF ratio responds to specific ANS manipulations. For instance, when posture is shifted from lying to sitting and then to standing, manoeuvres known to increase SNS and decrease PNS regulatory activity, the magnitude of the ratio has been found to increase correspondingly. So, when PNS activity is known, estimates of SNS activity can be achieved using the LF:HF ratio, which may also be used to evaluate whether any change in balance occurs in either a reciprocal or non-reciprocal fashion.

Pharmacological or surgical interception of PNS activity abolishes HF power and causes a reduction in the LF spectral component, not only in humans but also in horses, dogs and rats. Total, LF and HF spectral components also change chronically with ongoing illnesses, cardiac disease, age and other biological occurrences that effect autonomic activity and reactivity. For example, adult humans, when supine, show a progressive decline in total power with age while the LF:HF ratio remains fairly constant. The LF:HF ratio during postural changes increases as a function of age, indicating a reduction in autonomic reactivity in older subjects.

Horses have a characteristic pattern in their power spectra, with the HF band occurring between 0.07 and 0.60 Hz and the LF band at 0.01-0.07 Hz when resting. The spectral analysis of HRV in pigs closely resembles that in humans. The HF peak occurs between 0.1 and 0.5 Hz and the LF below 0.1 Hz. This is not surprising given the physiological similarities (e.g. mean HR and respiration rate) between adult humans and adult pigs. In adult cows, LF and HF reportedly occur between 0.0-0.25 Hz and 0.25-0.58 Hz, and in calves between 0.0-0.15 (LF) and 0.15-1.00 Hz (HF). The central location of either of these

frequency peaks may shift depending on the physiological status of the individual; nevertheless, the width of the bands is sufficiently broad to accommodate any such repositioning. Without controlled pharmacological manipulations (i.e. response curves) of ANS activity, it is difficult to pinpoint the precise location of these frequency peaks or predict how they will respond to **stress**.

HF power can also be expressed as a function of total spectral power ($HF/TOTAL = PNSI$), and LF power as a function of HF power ($LF/HF = SNSI$), to yield parasympathetic and sympathetic activity indicators, respectively. These normalized units of HF and LF power have been consistently reported to respond appropriately to repeated orthostatic challenges known to either increase SNS or decrease PNS regulatory control. Moreover, normalization reduces the effects due to alterations in total power and underscores the reciprocal or non-reciprocal relationship that reflects the different patterning of PNS and SNS regulatory control of the heart.

Heat stress

When the body is challenged with an elevated external temperature that begins to raise body temperature beyond the physiological homeostatic body temperature range, the animal is considered as being exposed to thermal stress. Thermal stress is a serious consideration for animal **welfare** because the inability to cope with this **stress** can rapidly lead to

P.311

suffering and **death**. Animals have a physiological thermal zone, termed the thermal comfort zone, which is a range of temperatures within which the body is able to effectively operate without invoking extraordinary measures. If the body temperature begins to exceed the upper critical temperature, then physiological and behavioural mechanisms are initiated that help to dissipate heat and bring the body back into its thermal neutral zone (**see also: Thermoregulation**).

To increase temperature loss, the animal's body will alter its vasculature to increase vasodilation to peripheral areas, such as the skin, to allow heat loss through convection, radiation and conduction. In addition, the animal will increase respiration and perspiration, if possible, to dissipate heat through evaporation. Increased cardiac output, including increased blood volume, will occur to increase heat transfer from the body core to the periphery. The animal will also invoke behavioural responses that aid in decreasing core body temperature. Many animals will seek shade and water to help cool the body. Swine, unable to sweat sufficiently, will enter water or a mud wallow to cool the body using evaporation. If the animal is in a windy environment, it may orient its body broadside to the wind to increase the surface area that is cooled. In all species appetite is typically depressed, which prevents further creation of heat from digestion. In modern livestock production, producers can incorporate artificial shade, high-

output fans and/or misters in their facilities to help keep animals cool. Livestock rapidly learn to use shade and misters during periods of elevated temperature.

Livestock are often able to withstand relatively hot conditions if given the chance to become accustomed to the heat slowly. Death losses of livestock in summer months typically occur from sudden spikes in environmental temperatures rather than from gradually increasing temperatures. Swine are especially susceptible to heat stress due to their typically high body fat content and their inability to sweat sufficiently. All livestock and poultry are at risk to heat stress when being transported. **Transport** of these species typically involves moving a large number of animals into a limited amount of space for the trip. In an environment that is not overly hot, these livestock can still succumb to heat stress and even death without proper ventilation. When environmental temperatures start to rise by even a few degrees, the temperature inside the transportation vehicles can reach critical values at an alarmingly fast rate. Therefore, during raised temperatures, all livestock and poultry should be transported during night-time.

Hedypagia

Hedypagia is the selection of food items according to the amount of pleasure derived from them, or their hedonic value. Natural selection has evolved mechanisms for animals to be satiated by foods that are good for them, but not by foods that do them harm or are of no benefit. The primary mechanism for discrimination between foods is by their taste, and four primary taste sensations have evolved to assist in this process: (i) sweetness for foods with high concentrations of simple carbohydrates; (ii) sourness for foods with a high acid:base ratio; (iii) saltiness for foods with high concentrations of sodium and, to a lesser extent, potassium; and (iv) bitterness for foods with potentially toxic organic compounds, e.g. many plant alkaloids. However, there is limited evidence that animals can recognize the inherent value of foods from their taste. They may adapt to potentially toxic or bitter compounds, however, and this could be due to increased hunger in the absence of alternative, safe, foods. They can also develop aversions to sweet foods. In relying on sensory feedback, the hypothesis of hedypagic selection does not often have sufficient regard for the post-ingestional consequences of the feed. (CJCP)

Herd health

The health of herds of farm animals, especially **cattle** and **pigs**, is an interaction between the animals, their environment and **disease**-causing organisms. As they are gregarious animals, cattle and pig herds should be considered not only as a group, but also as individuals, if the health of one animal differs markedly from that of the group. Bringing cattle or pigs indoors presents one of the most severe challenges to their health, as the contact between animals is increased and disease organisms are better able to survive in the more constant and generally benign environment compared with that outdoors. However, in the case of cattle, the nutrition of high-yielding cows may be better controlled, and their ability to rid themselves of pathogens may be better than if they were permanently at pasture, as the immune system functions best in a well-nourished animal.

The advent of widespread use of vaccines and antibiotics in the latter half of the 20th century heralded a low incidence of infectious diseases for most pigs and cattle, especially dairy cows, which are often treated annually at the end of lactation, as well as routinely when there is any evidence of bacterial infection. In the long term antibiotics will have limited value, as the ability of pathogenic bacteria to mutate and escape control is undoubtedly greater than our ability to find new antibiotics. Farmers must therefore be prepared to use more prophylactic and vaccination measures, such as reducing the stocking density of cattle and keeping them cleaner to prevent disease transfer.

Since the late 1950s, farm size has increased considerably in most cattle production systems in industrialized countries, as enterprises expand and small family farms are amalgamated into larger units (see: **Intensification of animal production**). Cattle are also more likely to be housed, often to the detriment of their welfare. The eradication of many disease organisms was achieved in the past through careful husbandry, but this was relaxed in the latter part of the 20th century with the perceived prospect of effective cures and better prevention strategies for most of the infectious diseases. The good husbandry that used to be essential for disease eradication is exemplified by the measures taken to prevent the spread of rinderpest more than 150 years ago in the UK:

- The byres of infected animals had to be washed and left empty for 2 months.
- Persons attending sick animals were prohibited from going near healthy stock.
- The sale of sick cattle was prohibited.
- Sick cattle were slaughtered and buried.
- All cases of the disease had to be reported.

P.312

These simple measures restricted the transmission of the disease and eventually led to its eradication in the UK. Nowadays, there is considerable movement of cattle and this reduces the effective immunity that develops for a range of pathogens in a specific area.

An alternative method of controlling disease is to reduce the stocking density of housed cattle and hence contact between animals. However, the reduction in output per unit area is only likely to be practical if product prices are increased or farmers are directly compensated for economic losses. Some reduction in cattle stocking density can be achieved through mixed farming systems, for example with **sheep**, because many pathogens are species-specific. However, the increased mechanization of farms has necessitated the adoption of simple farming systems, usually relying on the farming of single species of animals and crops (monoculture). It is a technological challenge for the future to design mixed farming systems that minimize disease risks but are still efficient users of land, labour and capital.

There are many challenges to the health of cattle, some of which have been long known, such as foot-and-mouth disease, **mastitis** and **lameness**, and some of which are new, such as *Escherichia coli* O157 and bovine spongiform encephalopathy (BSE). The type of **housing** is the dominant influence on the incidence of many of the common disorders of dairy cattle, especially lameness and mastitis.

Lameness

In relation to lameness, a scourge of modern housing systems, concrete wears the hooves more than earth, but the constant wetting of the foot in cubicle passageways covered in deep slurry can erode the soft heel bulb. This predisposes the cow to **laminitis**, and sometimes leads to the toes losing contact with the ground and unchecked growth (slipper foot). Excessive walking on concrete stretches the white line and wears the sole, thus weakening the bond between the wall and the sole. In straw yards the abrasion on the hoof is minimal, leading to increases in toe length until the cows are out at pasture. Interdigital infection is more common than in cubicle houses, as straw may be pushed up between the claws, causing a lesion that is open to infection, especially with *Phlegmona inter digitalis*. Excessive growth may close up the interdigital space, trapping dirt and causing infection. Long digits are common in modern cattle units, due partly to excessive growth as a result of the high nutrient density of their diet and partly to inadequate wear as a result of low levels of activity and a smooth concrete floor or soft strawed yard to walk on. Trimming reduces the load bearing of the heel, improves **locomotion** in cattle and reduces the hardness of the sole and abaxial wall. It is normally done by a method developed by Dutch cattlemen.

The condition of cow tracks can influence the prevalence of lameness in a herd. Stony, muddy tracks provide an uneven surface that can stress the sole and lead to lameness and poor welfare. The ideal surface is absorbent and provides a firm surface for walking on - bark chippings are recommended, but need constant care. They should be laid over a porous membrane and aggregate for good drainage. Concrete is very durable and is better than stony tracks, but not as comfortable underfoot as bark chippings. However, a concrete track can be used by both cows and vehicles, whereas if bark chippings are used, separate tracks are required because a vehicle's wheels will create ruts. Cows should never be hurried down a track by a herdsman using a dog or motorcycle.

Mastitis

Mastitis is an opportunistic infection of the mammary gland, the severity of which is dependent mainly on the delay in inflammatory response to the infection. It is not one disease, but a wide range of possible infections by up to 100 possible pathogens, making it a multifactorial disorder.

Mastitis causes a major reduction in the welfare of the cow, due to the fever that it induces, the localized pain in the mammary gland and the possible **stress of isolation** and treatment. The cost to the farmer is considerable, with losses arising for a number of reasons, including: (i) penalties imposed by the dairy purchasing the milk because it has a high somatic cell count (SCC); (ii) reduction in milk yield from the infected gland, which may persist into the subsequent lactation; (iii) withholding of the milk from sale after antibiotics have been applied; (iv) drug and veterinary costs; (v) reduced value of the affected cow; (vi) replacement costs; (vii) increased labour for managing the sick cow; and (viii) costs of associated diseases, in particular reproductive failure.

Mastitis also presents risks to human health, as milk containing antibiotics that is drunk by humans may induce bacterial resistance, or the consumption of unpasteurized milk contaminated with bacteria could lead to the consumer acquiring **zoonotic disease**. There are penalties in most countries for dairy farmers supplying milk contaminated with antibiotics, and insurance against this possibility is now available in some countries. Not only is milk contaminated with antibiotics unfit for human consumption, it is also unsuitable for cheese or yoghurt production, as the antibiotics impede the fermentation process. Dairy cows that contract mastitis before pregnancy is established have a delay in the interval to first service, on average about 3 weeks, and an average of one extra service is required for each conception.

Control measures for mastitis are based mainly on cleanliness and the regular use of antimicrobial chemicals and antibiotic drugs. They have been well established for at least 25 years and, if correctly implemented, should enable a dairy herd to have between 100,000 and 150,000 somatic cells/ml of milk in the bulk tank, fewer than 20 cases of mastitis/100 cows/305-day lactation, less than 12% of the herd infected at any one time and a recurrence rate of less than 6%. Fewer than five doses of antibiotics should be used for each case of clinical mastitis. These herd health targets, although attainable, may not in future be adequate for milk purchasers, who may devise species-specific penalties/incentive payments to regulate individual bacteria.

The continuing successful treatment of mastitis will require researchers to develop better control measures, as the bacteria will mutate and develop resistance to the current range of antibiotics. So far resistance has only been observed in response to *Staphylococcus aureus* infections when these are treated with penicillin or when cloxacillin is used for dry cow therapy. *S. aureus* infections during lactation are best controlled by clavulanate/amoxycillin, and for dry cow infections cloxacillin is still the best antibiotic to use. Most other

P.313

infections can be controlled with penicillin, although clavulanate/amoxycillin is best for *E. coli* infections. When an antibiotic is chosen, careful consideration needs to be given to the milk withdrawal time (from the time of insertion of the last tube). Some products are a combination of antibiotics. When using

antibiotic therapy on dry cows, the persistence should be noted, this ranging from 7 days for ampicillin to 42 days for cloxacillin.

The level of mastitis has not declined significantly since the late 1980s, despite widespread adoption of control measures, and in future there will probably be a return to an emphasis on maintaining cows in very clean conditions. This will be particularly relevant in controlling environmental pathogens, which have become more common as infectious pathogens have been largely brought under control by antibiotics. Slurry disposal will need to be carefully planned and attention paid to fly control and ventilation of buildings.

Heifers are particularly vulnerable to mastitis as their defences are not well developed, and they can exhibit twice the incidence of mastitis found in older cows. Infection chains from older cows to heifers are common, where bacterial infections are transmitted in the milking parlour.

Part of the reason why mastitis incidence has not declined relates to the increase in milk yields of cows in most areas. High-yielding cows tend to have wide teat canals, so the ingress of bacteria into the teat cistern is facilitated. Increasing milk yields through the injection of the growth hormone analogue (bovine somatotropin or BST) also increases mastitis. BST can stimulate the immune system in the mammary gland, but the extra mobilization of body tissues to support increased milk production may generally depress the immune function, leading to an increased mastitis frequency.

Herd health assurance schemes

There is increasing concern among the general public that farm conditions are not always satisfactory for the health and welfare of cattle. The other major concerns that the public may have are for food quality and environmental quality. Some of these concerned members of the public are prepared to pay more for cattle products that have been produced to an assured health standard (**see also: Farm assurance schemes**). Standards may be set by animal welfare charities, veterinary associations or large traders, such as the major supermarket chains, and by the government for specific diseases, e.g. enzootic bovine leucosis. Membership of such schemes may be required by the major supermarkets. Such standards will usually focus on the health of the herd and individuals within it, but also on related issues such as hygiene on the farm, the quality of housing, plant and equipment, feedstuff and water storage facilities, stockmanship and the ability of a farm to manage an emergency. Monitoring is on a regular basis and may be performed by veterinarians or, more usually, by staff specifically trained for the task, who have a checklist to examine different parts of the farm to assess their adequacy.

The underlying principles of most herd health assurance schemes are to ensure that the cattle have: (i) adequate space, in particular to allow for sufficient exercise indoors; (ii) freedom from aggression by other cattle, e.g. by providing adequate feeding and drinking facilities; (iii) adequate floors to walk on; (iv) a comfortable and clean bedded area; (v) regular veterinary care; (vi) competent supervision by stockpeople; and (vii) adequate transportation away from the farm where necessary. Herd health assurance schemes are useful not only to monitor disease frequency - to enable comparisons to be made with acceptable standards - but also to determine risk factors contributing to disease and to implement control measures to improve performance.

At the end of the 20th century, the desire for further improvement in the herd health status of cattle and limitation of the spread of disease, particularly zoonoses, led to the introduction of cattle-tracing systems, which became mandatory in the European Union member states from 1999. Under the system operating in the UK, cattle are required to have 'passports' that contain details of: (i) each animal's breed and sex; (ii) its date of birth and, eventually, its death; (iii) its dam's number and any movements that the animal has made throughout its life; and (iv) any government financial support that has been received for

the animal. The scheme enables government authorities to trace cattle easily if there is a disease outbreak and to assure members of the public that the authorities have control of cattle movements.

Never before have cattle diseases received so much attention from the public, veterinarians and farmers as in the years since the late 1980s. The farming industry has been repeatedly criticized for failing to provide a healthy product for consumption, and the government has been accused of not safeguarding human health and of not acting on scientific advice. From the difficulties that have been encountered, there is now emerging a system of dairy cattle monitoring and herd health care that should ensure a significant reduction in the risk to consumers, provided that the very considerable economic cost to the industry does not limit farmers' ability to implement the new measures. The systems put in place, such as the movement scheme and farm assurance schemes, should serve as a model for anyone wishing to reassure their consumers that beef and dairy products are safe foods to eat and that they have been produced in a high-welfare system, in relation to their physical needs, with attention paid to the environmental impact.

(CJCP)

Heritability

Some characteristics (phenotypes) are determined only by an organism's genes, while others are influenced by the environment as well as by genes. Eye colour in people is purely genetic, while milk yield of cows is partly genetic and partly a result of the action of the environment.

Heritability is a measure of the importance of genes in determining the value a characteristic may have. Eye colour is, effectively, 100% genetically determined, while milk yield in cows is much less genetically determined (it has a typical heritability of 25%). Heritabilities vary widely among different characters. For example, in beef cattle, survival from birth to weaning is only 5% heritable, while in sheep, greasy fleece weight is 60% heritable. The heritability of a particular character may differ at different stages of an animal's life, reflecting how the role of genes in determining the phenotype may change during the animal's development. Thus, in principle, an animal could be selected for breeding on the basis of its phenotype at a young age, but there might turn out to be no response to this selection because the role of genes in determining the phenotype at that age is only minor.

P.314
